Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

CONTENTS IN BRIEF

DECEMBER 1982 • VOLUME 50 • NUMBER 6

A note from the Editor-in-Chief, William C. Roberts, MD, appears on page A3 of this issue.

CORONARY HEART DISEASE

1199 **Effects of Carbon Dioxide, Nd-YAG, and Argon Laser Radiation on Coronary Atheromatous Plaques.** George S. Abela, Sigurd Normann, Donald Cohen, Robert L. Feldman, Edward A. Geiser, and C. Richard Conti

1206 **Transluminal Laser Catheter Angioplasty.** Daniel S. J. Choy, Simon Stertzer, Heidrun Z. Rotterdam, Nigel Sharrock, and Ivan P. Kaminow

1209 **Laser Coronary Angioplasty: Experience With 9 Cadaver Hearts.** Daniel S. J. Choy, Simon H. Stertzer, Heidrun Z. Rotterdam, and Michael S. Bruno

1212 **Prospective Evaluation of Radionuclide Angiocardiography for the Diagnosis of Coronary Artery Disease.** Erle H. Austin, Frederick R. Cobb, R. Edward Coleman, and Robert H. Jones

1217 **Serial Right Ventricular Thallium-201 Imaging After Exercise: Relation to Anatomy of the Right Coronary Artery.** Kenneth A. Brown, Charles A. Boucher, Robert D. Okada, H. William Strauss, Kenneth A. McKusick, and Gerald M. Pohost

1223 **Enhanced Transcardiac l-Norepinephrine Response During Cold Pressor Test in Obstructive Coronary Artery Disease.** Hiltrud S. Mueller, Parinam S. Rao, Pulipaka B. Rao, Dennis J. Gory, J. Gerard Mudd, and Stephen M. Ayres

1229 **The QT $>QS_2$ Syndrome: A New Mortality Risk Indicator in Coronary Artery Disease.** Harisios Boudoulas, Young Ho Sohn, William O'Neill, Roger Brown, and Arnold M. Weissler

1236 **Transaxial Tomography With Thallium-201 for Detecting Remote Myocardial Infarction. Comparison With Planar Imaging.** James L. Ritchie, David L. Williams, George Harp, John L. Stratton, and James H. Caldwell

1242 **Noninvasive Detection of Multivessel Disease After Myocardial Infarction by Exercise Radionuclide Ventriculography.** Alan G. Wasserman, Richard J. Katz, Patricia Cleary, Vijay M. Varma, Richard C. Reba, and Allan M. Ross

1248 **Importance of Coronary Risk Factors in the Presence or Absence of Myocardial Ischemia.** Markku Heliövaara, Martti J. Karvonen, Sven Punsar, and Jaason Haapakoski

1253 **Cold Pressor Thallium-201 Myocardial Scintigraphy in the Diagnosis of Coronary Artery Disease.** Masood Ahmad, Jerzy P. Dubiel, and Helmut Haibach

1258 **Plasma Beta-Thromboglobulin as a Measure of Platelet Activity. Effect of Risk Factors and Findings in Ischemic Heart Disease and After Acute Myocardial Infarction.** Charles W. Pumphrey and Joan Dawes

1262 **Use of QRS Scoring and Thallium-201 Scintigraphy to Assess Left Ventricular Function After Myocardial Infarction.** Nicholas L. DePace, Abdulmassih S. Iskandrian, A-Hamid Hakki, Sally A. Kane, and Bernard L. Segal

1269 **Current Incidence of Postmyocardial Infarction (Dressler's) Syndrome.** Edgar Lichstein, Edward Arsura, Gerald Hollander, Alvin Greengart, and Michael Sanders

1272 **Spontaneous Changes in Thallium-201 Myocardial Perfusion Imaging After Myocardial Infarction.** Andrew J. Buda, James D. Dubbin, Ian L. MacDonald, Hans D. Strauss, Sally A. Orr, and Harry Meindok

1279 **Assessment of the Use of the Age- and Sex-Specific United States Population as a Control Group for Analysis of Survival in Coronary Artery Disease.** Robert M. Califf, Kerry L. Lee, Frank E. Harrell, Jr., Sue Y. S. Kimm, Seymour Grufferman, and Robert A. Rosati

MISCELLANEOUS TOPICS

1283 **Improved Radiation Protection for Physicians Performing Cardiac Catheterization.** Edward W. Gertz, Judith A. Wisneski, Robert G. Gould, and John R. Akin

1287 **Compression of the Superior Vena Cava and Right Atrium in Cardiac Tamponade.** Stephen W. Miller, Laura Feldman, Igor Palacios, Robert E. Dinsmore, John B. Newell, Linda Gillam, and Arthur E. Weyman

1293 **Occlusive Thromboaortopathy (Takayasu's Disease) and Pregnancy. Clinical Course and Management of 33 Pregnancies and Deliveries.** Kaichiro Ishikawa and Shumpei Matsuura

1301 **Left Ventricular End-Systolic Stress-Shortening and Stress-Length Relations in Humans. Normal Values and Sensitivity to Inotropic State.** Kenneth M. Borow, Laurence H. Green, William Grossman, and Eugene Braunwald

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1309 **Electrophysiologic Testing in the Evaluation of Patients With Syncope of Undetermined Origin.** David S. Hess, Fred Morady, and Melvin M. Scheinman

1316 **Value of the H-Q Interval in Patients With Bundle Branch Block and the Role of Prophylactic Permanent Pacing.** Melvin M. Scheinman, Robert W. Peters, Mary Jane Sauvé, Jawahar Desai, Joseph A. Abbott, John Cogan, Barry Wohl, and Katherine Williams

1323 **Effects of Verapamil on the Electrophysiologic Properties of the Accessory Pathway in Patients With the Wolff-Parkinson-White Syndrome.** Richard W. Harper, Eric Whitford, Ken Middlebrook, Jack Federman, Stan Anderson, and Aubrey Pitt

1331 **Atrial Excitability and Conduction in Patients With Interatrial Conduction Defects.** Ross J. Simpson, Jr., James R. Foster, and Leonard S. Gettes

1338 **Termination of Ventricular Tachycardia. Evaluation of a New Pacing Method.** Martin J. Gardner, Harvey L. Waxman, Alfred E. Buxton, Michael E. Cain, and Mark E. Josephson

1346 **Termination of Ventricular Tachycardia: Role of Tachycardia Cycle Length.** Denis Roy, Harvey L. Waxman, Alfred E. Buxton, Francis E. Marchlinski, Michael E. Cain, Martin J. Gardner, and Mark E. Josephson

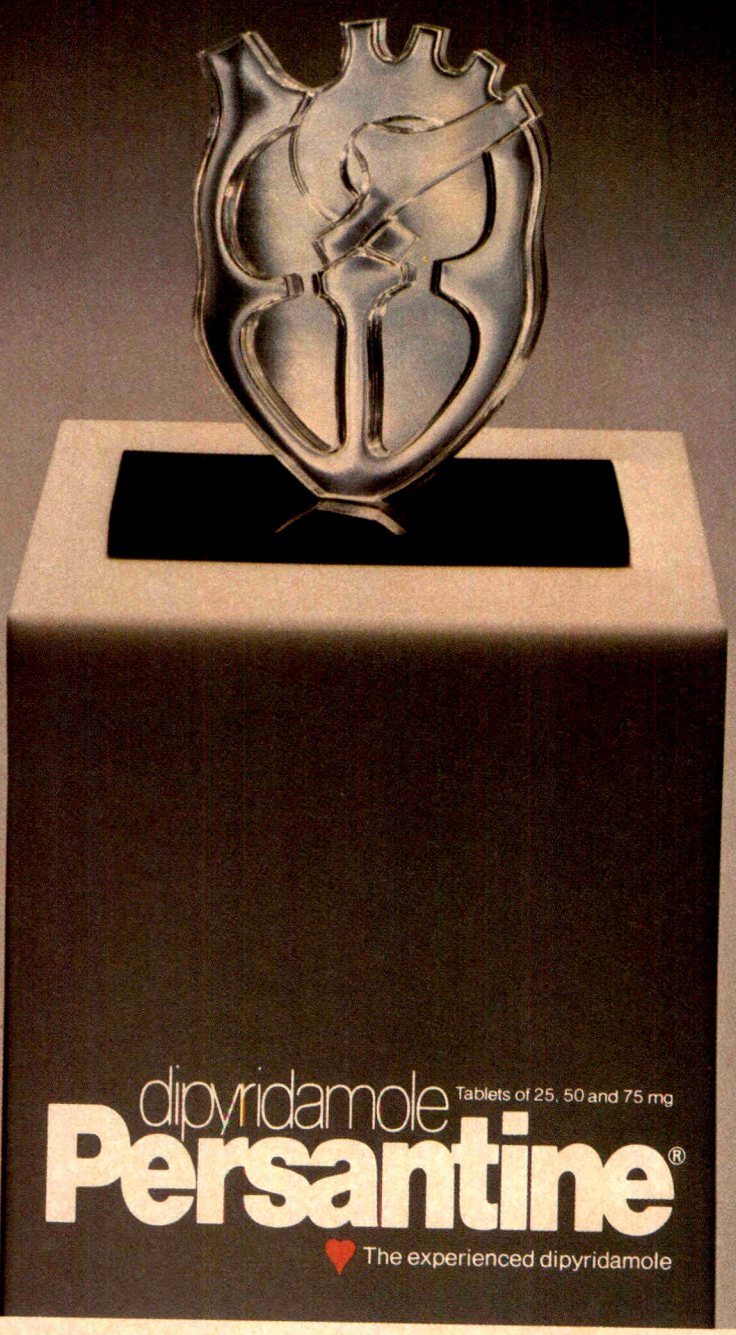
PERSANTINE®
at the heart of the cardiac* revolution



Under a commission from Boehringer Ingelheim Ltd., this striking model of the heart was created by George Giusti, noted sculptor and designer. Mr. Giusti has been awarded no fewer than ten gold and silver medals, and over 80 other awards and citations. His works have been depicted on the covers of such journals as *Fortune*, *Time* and *Holiday*, and his sculptures are found in the finest collections in this country.

A complimentary replica of "Miroir du Cœur" is available from your Boehringer Ingelheim representative.

* INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows: "Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack. Final classification of the less-than-effective indications requires further investigation.

)NTRAINDICATIONS—No specific contraindications are known.
ECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine lets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible lividuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.
VERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages.
tances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare es of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy.
those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by ssation of undesirable symptoms.
SAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses y be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before second or third month of continuous therapy. Tablets of 25, 50 and 75 mg. For complete details, please see the full prescribing information.

The Source.

Picker International is the source for cardiography systems.

To you, this is important.

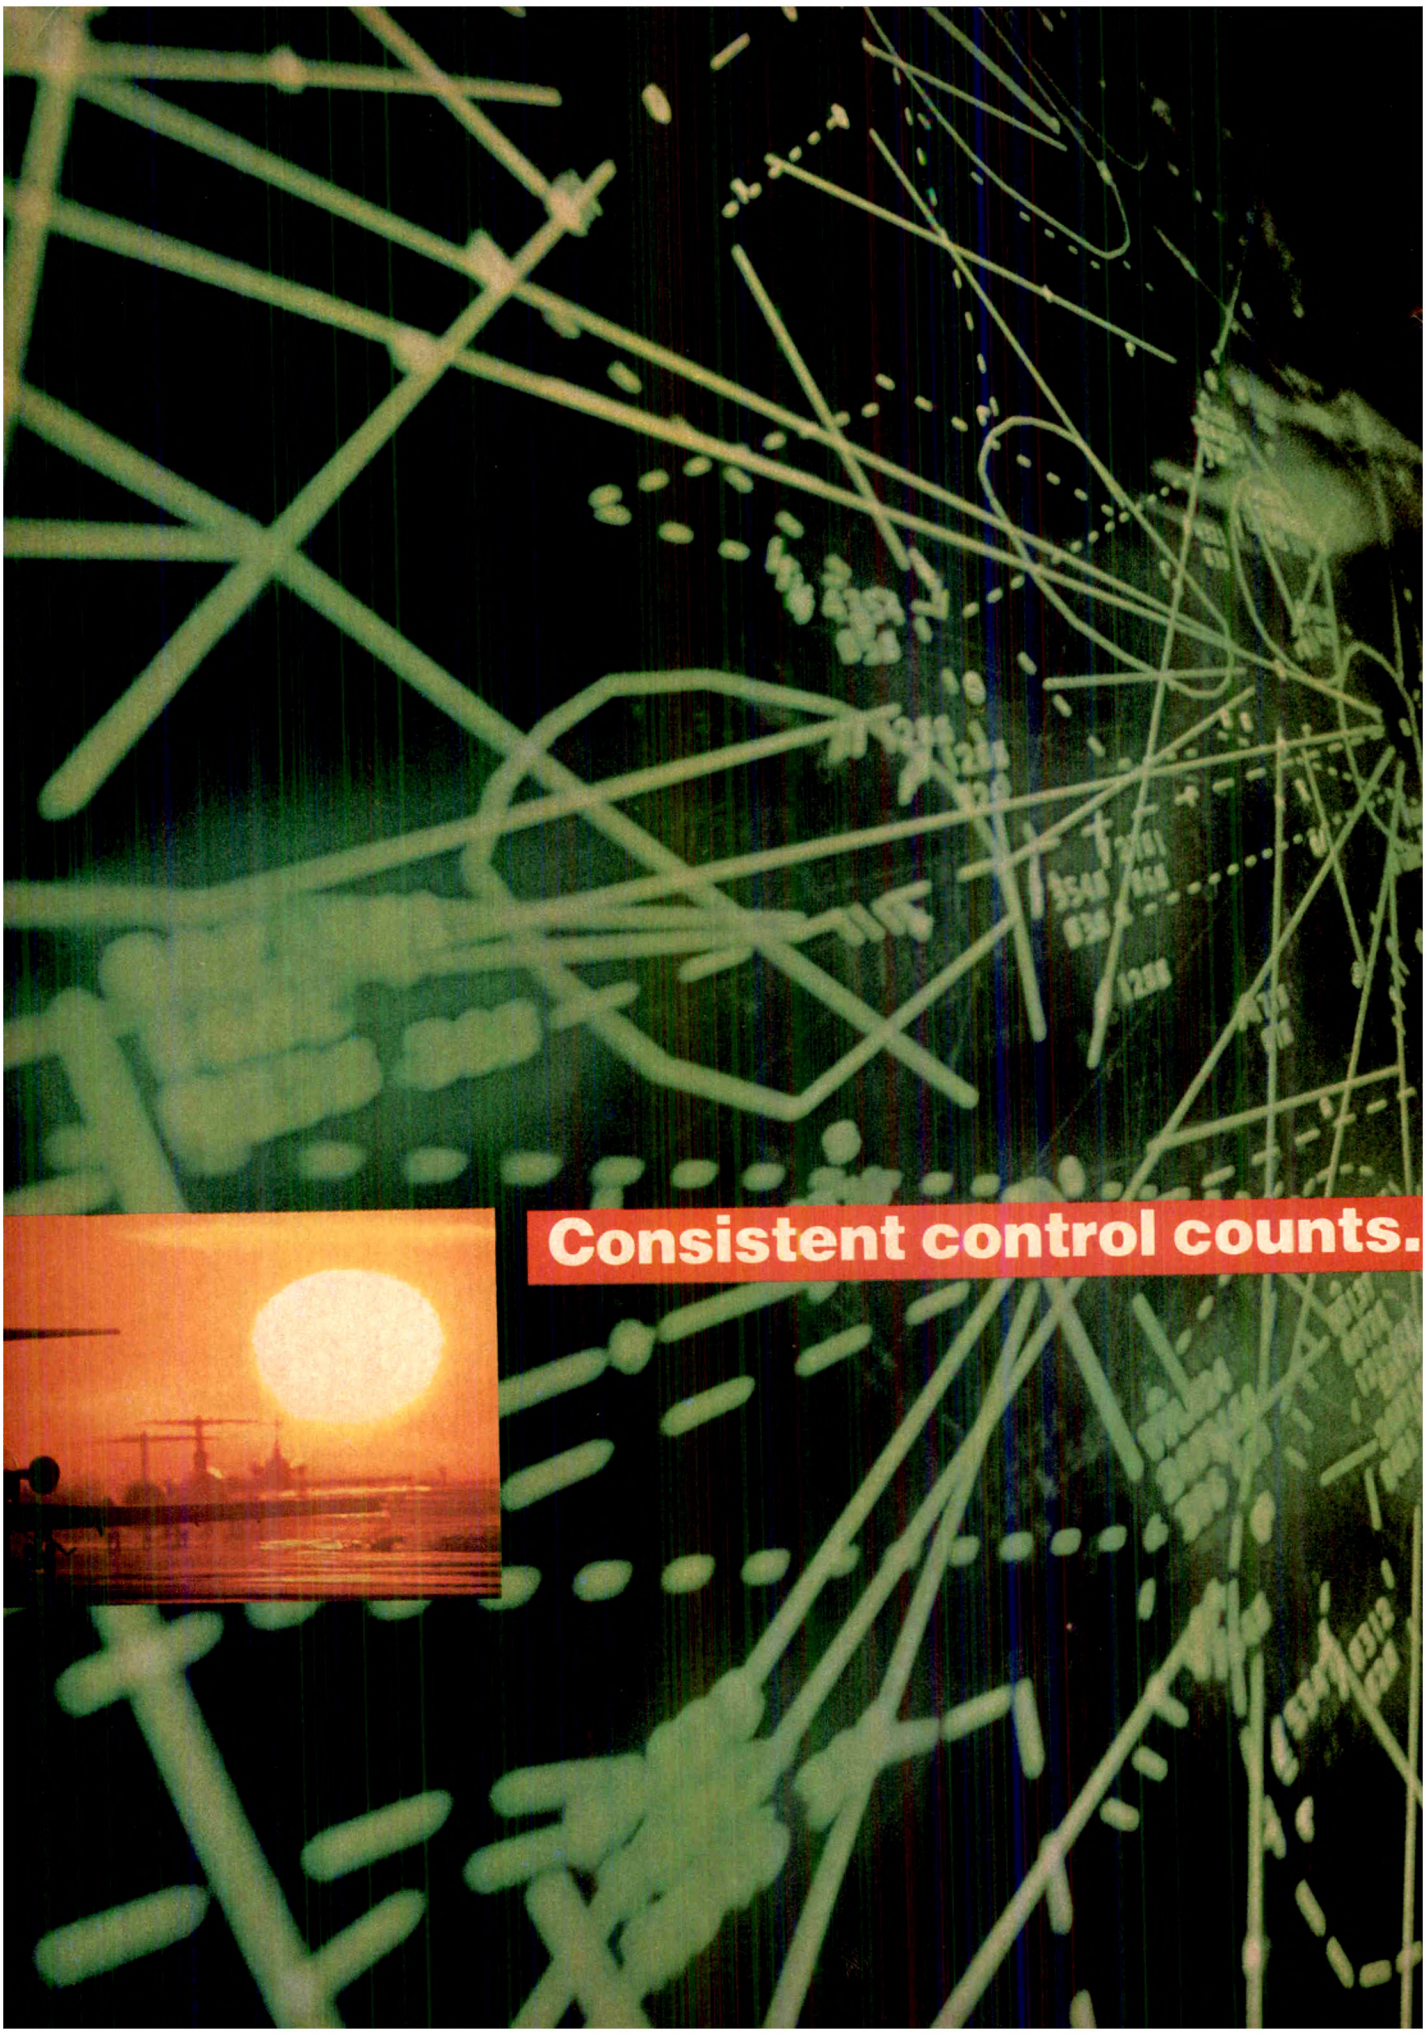
Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

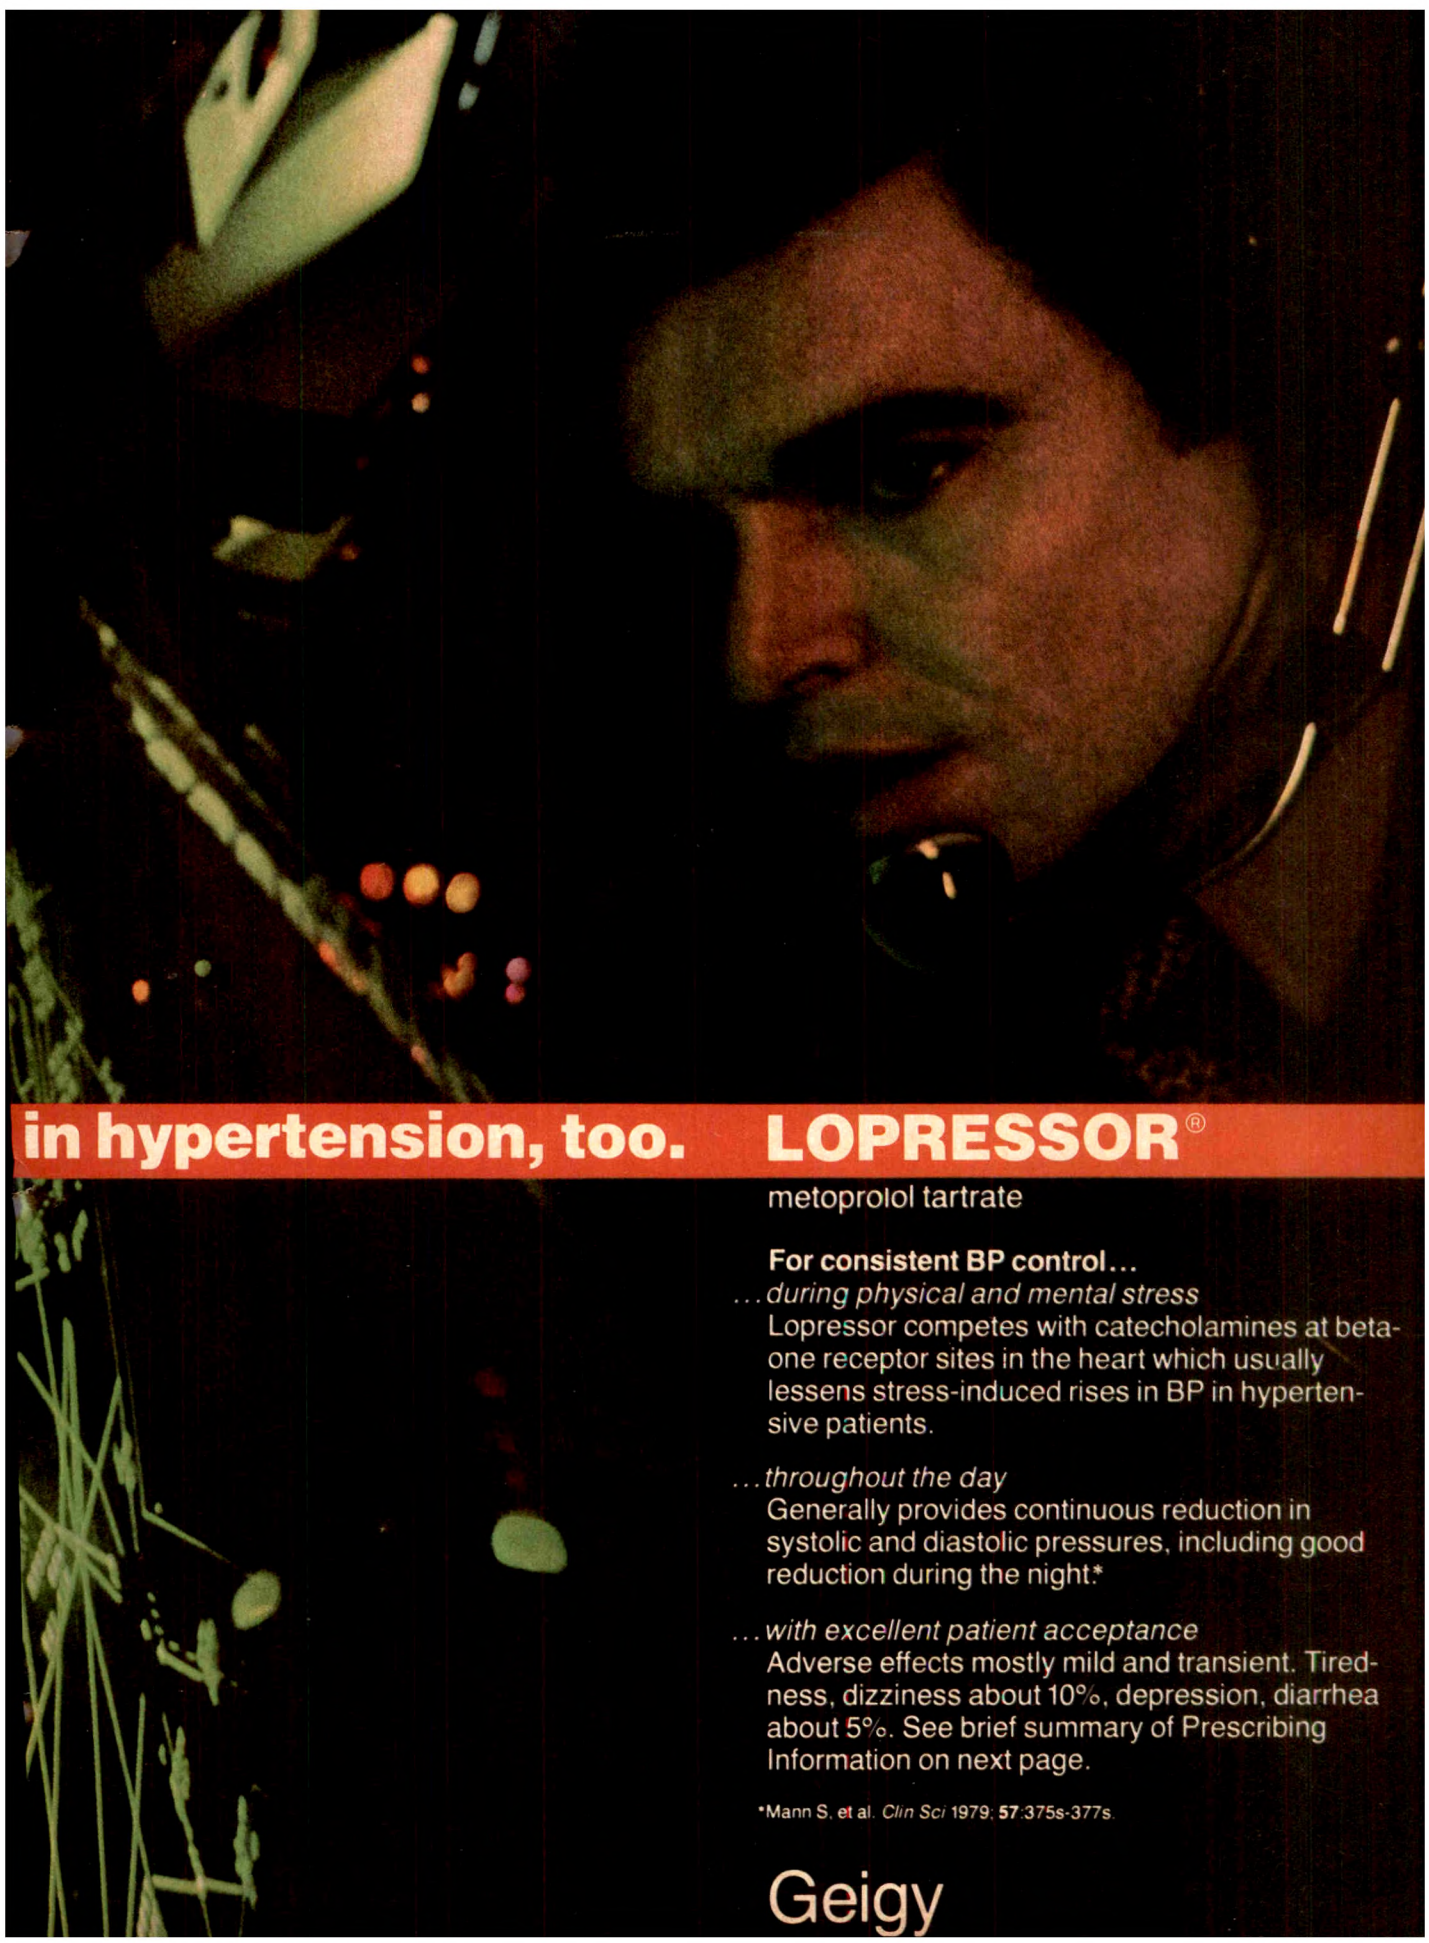
This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

PICKER INTERNATIONAL



Consistent control counts.



in hypertension, too. LOPRESSOR®

metoprolol tartrate

For consistent BP control...

...during physical and mental stress
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

...throughout the day
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

...with excellent patient acceptance
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.
Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).
Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.
In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.
Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.
Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute, a $beta_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**
Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.
Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.
Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.
Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.
Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.
Usage in Children: Safety and effectiveness in children have not been established.
Adverse Reactions Most adverse effects have been mild and transient.
Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.
Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**
Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**
Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.
Allergic: Pruritus has occurred in less than 1 of 100 patients.
Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.
Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.
Cardiovascular: Intensification of AV block (see **Contraindications**).
Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.
Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.
Miscellaneous: Reversible alopecia.
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.
Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta, selectivity diminishes as dosage of Lopressor is increased.
This drug should be stored at controlled room temperature and protected from moisture.
How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.
Store at controlled room temperature and protect from moisture.
Dispense in tight, light-resistant container (USP).

CORONARY HEART DISEASE

1199 Effects of Carbon Dioxide, Nd-YAG, and Argon Laser Radiation on Coronary Atheromatous Plaques

GEORGE S. ABELA, SIGURD NORMANN, DONALD COHEN, ROBERT L. FELDMAN, EDWARD A. GEISER, and C. RICHARD CONTI

The use of laser radiation in treatment of obstructive atherosclerotic disease has essentially been unexplored. This work describes the gross and histologic effects of laser radiation on human atherosclerotic plaques using split or intact arteries. Three different lasers (CO_2, Nd-Yag, and Argon) were used under different conditions (dry, immersed in saline or blood). The degree of damage to the atherosclerotic plaque and the underlying vessel wall was evaluated. A direct relation was observed between the energy used (power times duration of exposure) and the depth of penetration into the vessel wall. These preliminary observations suggest that laser radiation can destroy atherosclerotic obstructions and may have potential to recanalize occluded vessels.

1206 Transluminal Laser Catheter Angioplasty

DANIEL S. J. CHOY, SIMON STERTZER, HEIDRUN Z. ROTTERDAM, NIGEL SHARROCK, and IVAN P. KAMINOW

The first transluminal laser angioplasty in animals is reported. An Argon laser and a specialized coronary arterial catheter with a fiberoptic wave guide were used. Immediate histologic changes consisted of a moderate degree of intimal necrosis and some loss of elastic tissue. At 5 days the intima was repaired, but focal elastic tissue loss persisted.

1209 Laser Coronary Angioplasty: Experience With 9 Cadaver Hearts

DANIEL S. J. CHOY, SIMON H. STERTZER, HEIDRUN Z. ROTTERDAM, and MICHAEL S. BRUNO

Laser angioplasty in 16 coronary arteries in cadaver hearts is reported. Argon laser energy is conducted by way of a fiberoptic wave guide in an arterial catheter to the site of obstruction, and thrombi and plaque are vaporized. Successful laser angioplasty was achieved in 8 of 8 artificially thrombosed coronary arteries and in 6 of 7 coronary arteries naturally occluded with calcified plaque.

1212 Prospective Evaluation of Radionuclide Angiocardiography for the Diagnosis of Coronary Artery Disease

ERLE H. AUSTIN, FREDERICK R. COBB, R. EDWARD COLEMAN, and ROBERT H. JONES

The accuracy of rest and exercise radionuclide angiocardiography in the diagnosis of coronary artery disease was examined in this prospective study. Optimal criteria for the presence or absence of coronary disease had previously been derived from a retrospective analysis of 496 patients. In this study these same criteria were applied to 221 consecutive patients presenting with chest pain. Comparison with cardiac catheterization revealed a test sensitivity of 0.87 and a test specificity of 0.54. Thus, the sensitivity of radionuclide angiocardiography compares favorably with other noninvasive techniques for detecting ischemic heart disease. The poor specificity of the test, however, limits its overall accuracy.

CONTENTS

1217 Serial Right Ventricular Thallium-201 Imaging After Exercise: Relation to Anatomy of the Right Coronary Artery

KENNETH A. BROWN, CHARLES A. BOUCHER, ROBERT D. OKADA, H. WILLIAM STRAUSS, KENNETH A. McKUSICK, and GERALD M. POHOST

The relation of right ventricular appearance on exercise thallium-201 images to coronary artery anatomy was examined in 88 patients also undergoing coronary angiography for the evaluation of chest pain. Nonvisualization of right ventricular activity occurred in 10 patients. Nine of the 10 had significant stenosis of the proximal right coronary artery and 7 had high grade stenosis. Normal right ventricular appearance was found in 70 patients, 29 of whom had significant proximal right coronary artery disease. Right ventricular appearance was not affected by the presence or absence of left anterior descending or left circumflex artery disease. Thus, with exercise thallium-201 imaging, right ventricular transient defects suggest high grade proximal right coronary artery stenoses, and nonvisualization of right ventricular activity also suggests significant proximal right coronary disease. However, normal right ventricular appearance occurs frequently despite proximal right coronary artery disease, and does not exclude such disease.

1223 Enhanced Transcardiac l-Norepinephrine Response During Cold Pressor Test in Obstructive Coronary Artery Disease

HILTRUD S. MUELLER, PARINAM S. RAO, PULIPAKA B. RAO, DENNIS J. GORY, J. GERARD MUDD, and STEPHEN M. AYRES

Transcardiac l-norepinephrine responses during cold pressor test in 20 patients with normal coronary arteries were compared with those in 23 patients with abnormal coronary arteries (AC). Baseline hemodynamic data did not differ in the 2 groups, except for left ventricular end-diastolic pressure (mean ± standard deviation, 10 ± 3.7 (NC) and 15 ± 4.5 mm Hg (AC), $p < 0.01$). Baseline l-norepinephrine contents averaged 295 ± 152 (NC) and 250 ± 134 pg/ml (AC) in arterial blood, and 273 ± 152 and 250 ± 115 pg/ml in coronary sinus blood. Hemodynamic responses during cold stimulus were similar in the 2 groups. Also, cold pressor-induced increases in arterial and coronary sinus l-norepinephrine contents were balanced in NC patients, averaging 19 ± 30% and 17 ± 37%. In AC patients, however, a 26 ± 58% increase in arterial l-norepinephrine contents was associated with a 58 ± 62% increase in coronary sinus l-norepinephrine contents ($p < 0.02$), suggesting myocardial net release of l-norepinephrine. It is concluded that transcardiac l-norepinephrine responses during cold stimulus are enhanced in obstructive coronary artery disease.

1229 The QT $>QS_2$ Syndrome: A New Mortality Risk Indicator in Coronary Artery Disease

HARISIOS BOUDOULAS, YOUNG HO SOHN, WILLIAM O'NEILL, ROGER BROWN, and ARNOLD M. WEISSLER

In normal subjects electrical systole (QT) is shorter and closely parallels electromechanical systole (QS_2) throughout the range of resting heart rate. This association of QT to QS_2 prompted the hypothesis that the QT may be more physiologically linked to QS_2 than to heart rate and thus may provide a more potent prognostic indicator than the relation of QT to heart rate. To test this hypothesis 100 patients 14 months after myocardial infarction with an average follow-up of 43 months were studied. There were 20 patients with $QT > QS_2$ and 13 patients with long QT corrected for heart rate (QT_c). There were 20 deaths. The cumulative 5-year survival rate was 35% in patients with $QT > QS_2$ and 91% in patients with $QT \leq QS_2$ ($p < 0.01$); in the same cohort there was no significant difference in 5 year survival in patients with long or normal QT_c (69 versus 82%). Multivariate analysis revealed that the $QT > QS_2$ provides a prognostic indicator independent of the status of left ventricular performance or the extent of coronary artery disease.

Currently available antianginal agents...
and how they are most appropriately employed as

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

Synopsis of the Symposium

Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

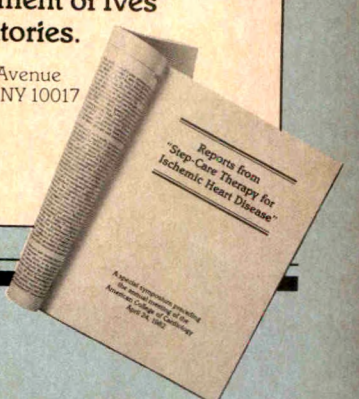
The complete Proceedings of the Symposium are available on request from the Professional Services Department of Ives Laboratories.

685 Third Avenue
New York, NY 10017



In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE) IS BASIC

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

IVES LABORATORIES INC.

New York, NY 10017

Dedicated to Improving the Quality of Life Through Medicine®

CLASSIFIED

Cardiologist wanted. High quality clinical cardiology practice in desirable South Florida location seeks board certified cardiologist. Prefer junior faculty member who desires to enter private practice. Excellent salary and benefits. Please send curriculum vitae and references to Box 235, The American Journal of Cardiology, 875 Third Ave., New York, N.Y. 10022.

CARDIOLOGIST

Needed to join an existing practice in a large multi-specialty clinic with co-located hospital on the West Coast of Florida. Excellent compensation and benefits. Send C.V. to: Box 225, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

equal opportunity employer m/f

HAMAD GENERAL HOSPITAL, a new 660 bed referral facility, invites applications from Board Certified Clinicians in:

Cardiology—Adult and Paediatric

Salaries are highly competitive and commensurate to clinical and academic experience. Contracts are for a three-year period.

Benefits include free accommodation, utilities, air tickets to and from Doha for a family of 5 (Dependent children to age 19), 60 days paid vacation, generous excess baggage allowances, Educational allowances and no Qatari income tax.

Please send complete Curriculum Vitae to: THE MEDICAL DIRECTOR, HAMAD GENERAL HOSPITAL, P.O. Box 3050, Doha, Qatar, Arabian Gulf.

FELLOWSHIP IN NON-INVASIVE CARDIAC IMAGING

The Massachusetts General Hospital announces a new fellowship in non-invasive cardiac imaging. This two year program is a collaborative effort of the Cardiac Unit, Cardiac Radiology and Nuclear Medicine. It is designed to provide clinical and basic research training in Echocardiography, Nuclear Cardiology, Nuclear Magnetic Resonance and Digital Radiography. Particular emphasis will be placed on the role of Computer Methods for Data and Image Storage, Retrieval and Analysis.

Applicants should have a firm commitment to cardiovascular research and have completed at least one year of clinical fellowship in Cardiology, Cardiac Radiology or Nuclear Cardiology. Applications are now being accepted for July 1, 1983.

For information and application write to:

Arthur E. Weyman, M.D.
Massachusetts General Hospital
Cardiac Ultrasound Laboratory
Boston, MA 02114

Northeastern Pennsylvania—Dynamic practice opportunity in cardiology available. Modern JCAH approved, 160 bed general acute care hospital forty-five minutes northwest of Allentown, Pennsylvania, provides outstanding potential and opportunity in excellent geographic location for building specialty practice. Please send resume to Tod Mammuth, NEEMA Medical Services, Inc. 399 Market Street, Philadelphia, PA 19106 or call 800-523-0776 (outside PA) or 215-925-3511 (in PA).

1236 Transaxial Tomography With Thallium-201 for Detecting Remote Myocardial Infarction. Comparison With Planar Imaging

JAMES L. RITCHIE, DAVID L. WILLIAMS, GEORGE HARP, JOHN L. STRATTON, and JAMES H. CALDWELL

Transaxial tomographic imaging with thallium-201 was compared with standard planar imaging in 38 patients with remote myocardial infarction and 15 nomal patients. The set of transverse-section images was reformatted by 3-dimensional interpolation to obtain tomograms along the long and short axes of the myocardium. Tomographic and planar images were interpreted qualitatively. Overall, tomography detected 87% of previous infarctions while planar imaging detected 63% ($p = 0.01$). The improvement of the tomographic imaging method occurred only in the combined subset of transmural inferior and subendocardial infarctions, and not transmural anterior infarctions. Fourteen of 15 patients without infarction were normal on both planar and tomographic imaging. One normal patient had a defect by both techniques, yielding a specificity of 93% for each. It is concluded that transaxial tomography significantly improves the detection of thallium-201 myocardial perfusion defects in patients with previous myocardial infarction.

1242 Noninvasive Detection of Multivessel Disease After Myocardial Infarction by Exercise Radionuclide Ventriculography

ALAN G. WASSERMAN, RICHARD J. KATZ, PATRICIA CLEARY, VIJAY M. VARMA, RICHARD C. REBA, and ALLAN M. ROSS

Exercise radionuclide ventriculography for the detection of multivessel coronary artery disease was assessed in 74 patients surviving a first myocardial infarction. Of 38 patients with previous inferior infarction, the mean exercise ejection fraction increased from rest ($3 \pm 2.5\%$) in 13 patients with single-vessel disease but decreased ($5.2 \pm 1.4\%$) in 25 patients with multivessel disease ($p < 0.01$). Among 36 patients with previous anterior infarction there was no significant difference in the response to exercise in those with single- and multivessel disease. The sensitivity and specificity of predicting multivessel disease by the criterion of decreasing the exercise ejection fraction by $\geq 5\%$ or the development of a new wall motion abnormality were 80% and 92%, respectively, for patients with inferior infarction but only 69% and 40% for those with anterior infarction. These results suggest that exercise radionuclide ventriculography can discriminate single- and multivessel disease after an inferior but not an anterior myocardial infarction.

1248 Importance of Coronary Risk Factors in the Presence or Absence of Myocardial Ischemia

MARKKU HELIÖVAARA, MARTTI J. KARVONEN, SVEN PUNSAR, and JAASON HAAPAKOSKI

Smoking history, systolic blood pressure, and serum cholesterol concentration were studied for their prediction of 5-year coronary mortality in middleaged and older Finnish men who had initially been classified into 3 groups according to degree of myocardial ischemia: (1) previous myocardial infarction, (2) ischemic heart disease without infarction, and (3) no myocardial ischemia. The risk factors were associated, independently of each other and of age, with the relative risk of coronary death similarly in the 3 groups, whereas their absolute impact on mortality was strongly pronounced among the men with ischemic heart disease, and even more so among those with a previous myocardial infarction. The results suggest that seconday prevention of ischemic heart disease may be important.

1253 Cold Pressor Thallium-201 Myocardial Scintigraphy in the Diagnosis of Coronary Artery Disease

MASOOD AHMAD, JERZY P. DUBIEL, and HELMUT HAIBACH

Thallium-201 myocardial scintigraphy was performed during cold pressor stimulation in 36 patients, 31 with coronary artery disease and 5 with normal coronary angiograms. Transient perfusion deficits were noted in 24 of 31 patients with coronary artery disease (sensitivity 77%), and scintigrams were normal in all 5 patients without coronary artery disease. Exercise electrocardiograms were positive for ischemia in 18 of 24 patients with and in 1 of 5 patients without coronary artery disease (sensitivity 75% and specificity 80%). Exercise thallium-201 scintigrams, obtained in 16 patients, detected all 11 patients with coronary artery disease and were normal in the 5 without such disease. Coronary cineangiograms performed during cold pressor stimulation in 6 patients who had positive cold pressor and exercise thallium-201 scintigrams showed no coronary spasm. The data indicate that cold pressor thallium-201 scintigraphy offers promise as a noninvasive test in the diagnosis of coronary artery disease, especially in patients in whom exercise testing is not feasible.

LIBRARY

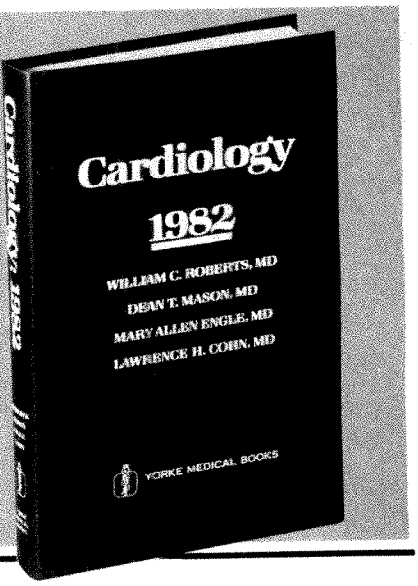
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

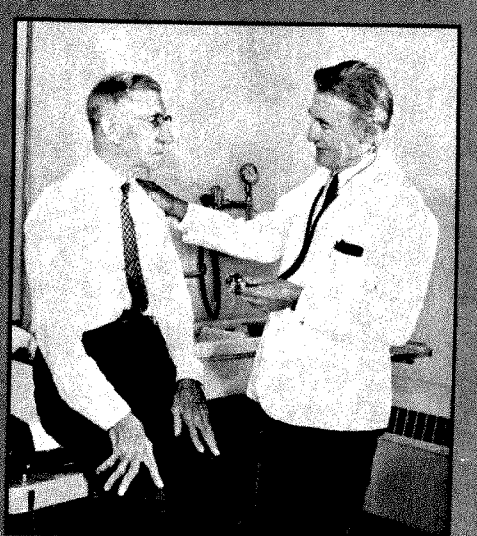
Vascular conditions can present severe diagnostic challenges to even the most experienced clinician.



Vascular conditions such as pulmonary embolism and aortic dissection are often difficult to diagnose. That's why you'll find this title in the Cardiovascular Clinics to be particularly valuable.

Volume 13, Number 2 Cardiovascular Clinics

CLINICAL VASCULAR DISEASE

You'll find wide ranging coverage of virtually every common and uncommon manifestation of peripheral and occlusive vascular disease encountered in a clinical situation. Practical diagnostic and therapeutic principles are stressed in every chapter.

Of particular interest:
- cerebrovascular disease
- surgical treatment of occlusive arterial disease
- balloon angioplasty
- antithrombotic therapy
- diagnosis of leg ulcer
- differential diagnosis of edema
- aneurysmal disease.

Guest Editor: **John A. Spittell, Jr.,** MD, FACP, FACC, Mary Lowell Leary Professor of Medicine, Mayo Medical School; Consultant, Cardiovascular Diseases and Internal Medicine, Mayo Clinic; with 22 other contributors. About 330 pp., 155 ill. Ready Jan. 1983. About $45.00.

Contents: Principles of Conservative Treatment of Occlusive Arterial Disease • Chronic Occlusive Arterial Disease of the Lower Extremities • Principles and Techniques of Occlusive Arterial Disease of the Lower Extremities • Acute Arterial Occlusion • Occlusive Arterial Disease in the Upper Extremity • Vasospastic Disorders • Aneurysmal Disease • Aortic Dissection • Acute Venous Thrombosis • Chronic Venous Insufficiency • Pulmonary Embolism • Differential Diagnosis of Leg Ulcer • Occlusive Cerebral Arterial Disease • Occlusive Renovascular Disease • A Perspective of Percutaneous Transluminal Angioplasty • The Vasculitides • Lymphedema • Differential Diagnosis of Edema of the Lower Extremities • Antithrombotic Therapy.

Also of Interest:

Controversies in Coronary Artery Disease, Cardiovascular Clinics, Volume 13, Number 1

This fascinating volume offers the opinions of leading medical authorities on 18 current and controversial issues relating to coronary artery disease. Although the experts may disagree, each point of view is based on sound medical facts.

Guest Editor: **Shahbudin H. Rahimtoola, MD,** Professor of Medicine, Chief Section of Medicine Cardiology, University of Southern California, Los Angeles, Calif.; with 38 other contributors. 367 pp. 140 ill. September 1982. $45.00.

A Guide to Cardiac Pacemakers

In one single, lavishly illustrated source, **A Guide to Cardiac Pacemakers** answers your many questions concerning the profusion of pacemakers available today. It covers all the major topics, including operational variations, functional time variations, manufacturers and their models, and radiologic identification of a pacemaker in a patient.

Edited by **Dryden Morse, MD; Robert M. Steiner, MD;** and **Victor Parsonnet, MD.** About 380 pp., 400 ill. Ready April 1983. About $65.00.

Cardiac Surgery, Cardiovascular Clinics, Volume 12, Number 3

In this outstanding new book, leading authorities discuss in depth the topics that are of vital concern to cardiologists and cardiovascular surgeons. They offer you practice-applicable advice on which forms of cardiac disease can be remedied surgically, how successfully, and with what sequelae.

Guest Editor: **Dwight C. McGoon,** MD, Professor of Surgery and Cardiology, Mayo Clinic, Rochester, Minnesota; with 45 other contributors. 242 pp. Illustd. January 1982. $40.00.

The Editor-in-Chief of the Cardiovascular Clinics is **Albert N. Brest,** MD.

I would like to receive the indicated books on 30-day approval.

1258 Plasma Beta-Thromboglobulin as a Measure of Platelet Activity. Effect of Risk Factors and Findings in Ischemic Heart Disease and After Acute Myocardial Infarction

CHARLES W. PUMPHREY and JOAN DAWES

Mean plasma beta-thromboglobulin was found to be increased in 104 patients with ischemic heart disease, compared with that in 101 controls. Smoking, hyperlipidemia, or both risk factors together in otherwise normal individuals were not associated with elevated levels suggesting that risk factors, per se, do not activate platelets. However, the presence of 2 or more risk factors in patients with ischemic heart disease was associated with significantly higher levels than those found in patients with only 1 or no risk factors. This suggests that platelets are activated by the presence of extensive vascular disease. The plasma levels of beta-thromboglobulin in patients with acute myocardial infarction or unstable angina did not change significantly in the days after their admission. Thus the measurement of systemic plasma beta-thromboglobulin indicates the total level of platelet activity in the circulation but is not sufficiently sensitive to provide information about local events.

1262 Use of QRS Scoring and Thallium-201 Scintigraphy to Assess Left Ventricular Function After Myocardial Infarction

NICHOLAS L. DePACE, ABDULMASSIH S. ISKANDRIAN, A-HAMID HAKKI, SALLY A. KANE, and BERNARD L. SEGAL

In this study a statistically significant correlation was found between 3 independent methods for assessing the size of acute myocardial infarction: the QRS score, the size of the resting thallium-201 perfusion defect, and left ventricular ejection fraction. However, in chronic infarction the QRS score was not useful in predicting the ejection fraction; although in these patients a fair correlation was still present between the ejection fraction and the size of the thallium perfusion defect. These data indicate that the size of the defect is related to the ejection fraction in patients with acute or chronic infarction. The QRS score in acute infarction and size of the thallium defect in acute or chronic infarction can categorize patients into those who have low, moderate, and normal ejection fraction.

1269 Current Incidence of Postmyocardial Infarction (Dressler's) Syndrome

EDGAR LICHSTEIN, EDWARD ARSURA, GERALD HOLLANDER, ALVIN GREENGART, and MICHAEL SANDERS

In this study 282 patients with documented acute myocardial infarction were examined. Early postmyocardial infarction pericarditis was seen in 18 patients (6.4%). Information concerning the patient's status was available at 6 months in 229 patients who were discharged alive. There were no documented cases of Dressler's syndrome. We suggest that this decreased incidence or disappearance of Dressler's syndrome is most likely related to decreased use of oral anticoagulants and more aggressive therapy of postmyocardial infarction pericarditis.

1272 Spontaneous Changes in Thallium-201 Myocardial Perfusion Imaging After Myocardial Infarction

ANDREW J. BUDA, JAMES D. DUBBIN, IAN L. MacDONALD, HANS D. STRAUSS, SALLY A. ORR, and HARRY MEINDOK

Changes in regional myocardial perfusion after myocardial infarction have not been investigated extensively. In this study 26 patients underwent exercise thallium-201 myocardial perfusion imaging 3 weeks and 3 months after myocardial infarction. A semiquantitative scoring scheme was used to assess the thallium-201 perfusion scan in 5 regions on each of 3 views. The stress thallium-201 score increased significantly (44.3 $\pm$ 1.2 to 48.3 $\pm$ 1.1, $p < 0.001$) between 3 weeks and 3 months after infarction. The redistribution thallium-201 scores did not change in this same interval. These results indicate that spontaneous improvements in thallium-201 myocardial perfusion imaging may occur in patients after myocardial infarction. This improvement may be related to dynamic changes in coronary perfusion such as spontaneous recanalization or collateral development.

Dobutamine/Dobutrex®

Dobutamine HCl

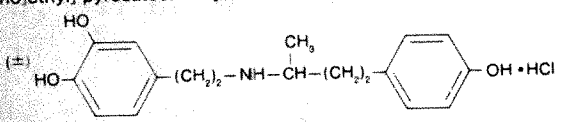
Description: Dobutrex is (±)-4-[2-[[3-(*p*-hydroxyphenyl)-1-methylpropyl] amino]ethyl]-pyrocatechol hydrochloride. It is a synthetic catecholamine.



Molecular Formula: $C_{18}H_{23}NO_3 \cdot HCl$ Molecular Weight: 337.84

The clinical formulation is supplied in a sterile lyophilized form for intravenous use only. Each vial contains 250 mg of dobutamine and 250 mg of mannitol. Hydrochloric acid is used to adjust the *p*H. The *p*H of the reconstituted solution is between 2.5 and 5.5.

Clinical Pharmacology: Dobutrex is a direct-acting inotropic agent whose primary activity results from stimulation of the beta receptors of the heart while producing comparatively mild chronotropic, hypertensive, arrhythmogenic, and vasodilative effects. It does not cause the release of endogenous norepinephrine, as does dopamine. In animal studies, dobutamine produces less increase in heart rate and less decrease in peripheral vascular resistance for a given inotropic effect than does isoproterenol.

In patients with depressed cardiac function, both dobutamine and isoproterenol increase the cardiac output to a similar degree. In the case of dobutamine, this increase is usually not accompanied by marked increases in heart rate (although tachycardia is occasionally observed), and the cardiac stroke volume is usually increased. In contrast, isoproterenol increases the cardiac index primarily by increasing the heart rate while stroke volume changes little or declines.

Facilitation of atrioventricular conduction has been observed in human electrophysiologic studies and in patients with atrial fibrillation.

Systemic vascular resistance is usually decreased with administration of dobutamine. Occasionally, minimum vasoconstriction has been observed.

Most clinical experience with dobutamine is short-term—up to several hours in duration. In the limited number of patients who were studied for 24, 48, and 72 hours, a persistent increase in cardiac output occurred in some, whereas the output of others returned toward base-line values.

The onset of action of Dobutrex is within one to two minutes; however, as much as ten minutes may be required to obtain the peak effect of a particular infusion rate.

The plasma half-life of dobutamine in humans is two minutes. The principal routes of metabolism are methylation of the catechol and conjugation. In human urine, the major excretion products are the conjugates of dobutamine and 3-O-methyl dobutamine. The 3-O-methyl derivative of dobutamine is inactive.

Alteration of synaptic concentrations of catecholamines with either reserpine or tricyclic antidepressants does not alter the actions of dobutamine in animals, which indicates that the actions of dobutamine are not dependent on presynaptic mechanisms.

Indications and Usage: Dobutrex is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to institution of therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add another 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstitution time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250, 500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

How Supplied: Vials Dobutrex® (dobutamine hydrochloride, Lilly), for Injection (lyophilized), equivalent to 250 mg dobutamine, 20-ml size, rubber-stoppered, in packages of 1. [121979]

1279 Assessment of the Use of the Age- and Sex-Specific United States Population as a Control Group for Analysis of Survival in Coronary Artery Disease

ROBERT M. CALIFF, KERRY L. LEE, FRANK E. HARRELL, Jr., SUE Y. S. KIMM, SEYMOUR GRUFFERMAN, and ROBERT A. ROSATI

The age- and sex-specific United States population was evaluated as a control group for analysis of the survival of patients with coronary artery disease. The survival of medically treated patients as a group was lower than corresponding age- and sex-specific U.S. population rates. However, the survival of patients with normal left ventricular contraction and stable chest pain was similar to the age- and sex-specific population survival rates. Even after removing deaths due to ischemic heart disease from the general population, the survival of patients with normal coronary arteries exceeded the age- and sex-specific population survival. Due to biases inherent in the selection of patients for cardiac catheterization and the presence of other serious diseases in persons in the general population, the age- and sex-specific U.S. population is not an adequate control group for rigorous analysis of the effect of therapy in coronary artery disease.

MISCELLANEOUS TOPICS

1283 Improved Radiation Protection for Physicians Performing Cardiac Catheterization

EDWARD W. GERTZ, JUDITH A. WISNESKI, ROBERT G. GOULD, and JOHN R. AKIN

This study assesses the potential radiation exposure to physicians performing cardiac catheterization using a Poly C Diagnost System. The radiation exposure to the eyes and thyroid is considerably increased using the left anterior oblique-cranial view compared with the traditional right and left anterior oblique views. To reduce such exposure, a ceiling-suspended shield (60 × 45 cm) was developed. This shield was found effective in significantly reducing (>85%) the physician's radiation exposure in all angulations.

1287 Compression of the Superior Vena Cava and Right Atrium in Cardiac Tamponade

STEPHEN W. MILLER, LAURA FELDMAN, IGOR PALACIOS, ROBERT E. DINSMORE, JOHN B. NEWELL, LINDA GILLAM, and ARTHUR E. WEYMAN

In an attempt to identify specific angiographic patterns that might be useful in distinguishing cardiac tamponade from constrictive pericarditis and other causes of right atrial hypertension, the angiographic and hemodynamic characteristics of 10 patients with cardiac tamponade were compared with similar characteristics in a group of patients with either constrictive pericarditis, effusive-constrictive pericarditis, or pericardial effusion with left ventricular failure. Two predictive angiographic patterns of cardiac tamponade were noted: (1) a tapering or local lateral indentation of the intrapericardial portion of the superior vena cava, and (2) an exaggerated phasic variation in the diameter of the superior vena cava at its junction with the right atrium. Two-dimensional echocardiographic studies in an additional group of 10 patients with cardiac tamponade demonstrated marked concavity of the right atrial free wall corresponding to the angiographic abnormality.

1293 Occlusive Thromboaortopathy (Takayasu's Disease) and Pregnancy. Clinical Course and Management of 33 Pregnancies and Deliveries

KAICHIRO ISHIKAWA and SHUMPEI MATSUURA

The data presented assist in predicting the outcome of pregnancy and delivery and serve as a guide to the management of patients with occlusive thromboaortopathy, a chronic inflammatory arteriopathy of unknown cause. Although pregnancy did not enhance the inflammatory activity, various cardiovascular events occurred in the perinatal period. During the intrapartum uterine contractions, there was a marked increase in systolic blood pressure in 10 pregnancies of the 22, including 1 pregnancy in a patient who subsequently had a cerebral hemorrhage. There were no maternal or neonatal deaths; however, intrauterine growth of the fetus was retarded when the mothers had severe complications. A prepregnant evaluation of the disease, planning the mode of delivery from both obstetric and nonobstetric indications, and intrapartum and anesthetic considerations, with special reference to the measurement of blood pressure, are important. In addition, reported data on 50 pregnancies in 46 women with Takayasu's disease are reviewed.

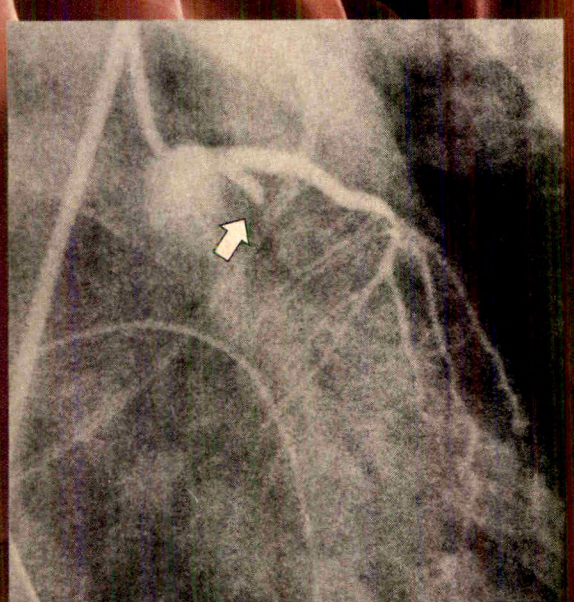
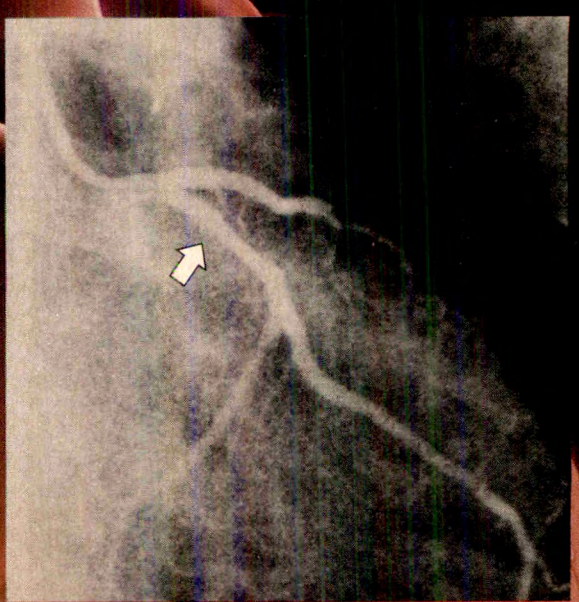
In evolving transmural myocardial infarction

New therapy quickly dissolves acute coronary artery thrombi



Pre-streptokinase
A 38-year-old woman in cardiogenic shock with acute lateral wall myocardial infarction caused by complete left



Post-streptokinase
The left circumflex is now widely patent beyond previous site of obstruction (arrow).

Please see full prescribing information, a summary

STREPTASE®
(streptokinase)

now indicated for acute coronary artery thrombosis.

Streptase® is infused directly into the involved artery during cardiac catheterization.

Efficacy demonstrated in multicenter studies

Coronary artery reperfusion was accomplished in 174 of 221 patients (79%) during evolving transmural myocardial infarction.

Randomized, controlled studies are in progress to determine the effects of reperfusion on salvage of myocardial tissue and reduction of mortality.

Side effects: few and readily controlled

There were no reports of allergic reaction or fever. Seven cases of bleeding at the puncture site and one case of moderate peritoneal bleeding were controlled without terminating therapy. Severe bleeding was reported in only one patient. This patient had a gastric ulcer six months prior to treatment.

Prompt initiation of treatment critical

The greatest benefit is achieved when therapy is initiated within six hours after the onset of symptoms.

Thrombolytic activity and safety record well documented

Streptase® has been effectively used worldwide for nearly a decade. Its record of clinical success is well matched by its record of safety, and both have been extensively reported in the medical literature.

STREPTASE®
(streptokinase)

A major advance in M.I. therapy

Please see full prescribing information, a summary of which appears on the following page.

STREPTASE® (streptokinase)
Brief Summary
CONSULT PACKAGE INSERT FOR FULL PRESCRIBING INFORMATION.

INDICATIONS AND USAGE

CORONARY ARTERY THROMBOSIS

Streptase® (streptokinase) has been reported to lyse acute thrombi obstructing coronary arteries, associated with evolving transmural myocardial infarction. Diagnosis of acute myocardial infarction has been confirmed, and the site of coronary thrombosis identified by selective coronary angiography. Other studies have demonstrated that (a) a thrombus is present in approximately 90% of patients evaluated within four hours of onset of symptoms; (b) when compared to concurrent or historical controls, the majority of patients who received intracoronary streptokinase within 6 hours of onset of symptoms showed a more immediate recanalization (within a few minutes vs hours/days) of the involved vessel.

IT HAS NOT BEEN ESTABLISHED THAT INTRACORONARY ADMINISTRATION OF STREPTOKINASE DURING EVOLVING TRANSMURAL MYOCARDIAL INFARCTION RESULTS IN SALVAGE OF MYOCARDIAL TISSUE, NOR THAT IT REDUCES MORTALITY. CONTROLLED STUDIES ADDRESSING THESE PARAMETERS ARE IN PROGRESS AND UNTIL COMPLETED, THOSE PATIENTS WHO MIGHT BENEFIT FROM THIS THERAPY CANNOT BE DEFINED.

CONTRAINDICATIONS

Because thrombolytic therapy increases the risk of bleeding, Streptase® (streptokinase) is contraindicated in the following situations:

- active internal bleeding
- recent (within 2 months) cerebrovascular accident, intracranial or intraspinal surgery (see WARNINGS)
- intracranial neoplasm

WARNINGS

Bleeding

The aim of Streptase® (streptokinase) therapy is the production of sufficient amounts of plasmin for the lysis of intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example, at sites of needle punctures, are also lysed and bleeding from such sites may occur.

Intramuscular injections and nonessential handling of the patient must be avoided during treatment with Streptase® (streptokinase). Venipunctures should be performed carefully and as infrequently as possible.

Should an arterial puncture be necessary during intravenous therapy, upper extremity vessels are preferable. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

When internal bleeding occurs, it may be more difficult to manage than that which occurs with conventional anticoagulant therapy.

In the following conditions the risks of therapy may be increased and should be weighed against the anticipated benefits.

- Recent (within 10 days) major surgery, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels
- Recent serious gastrointestinal bleeding (within 10 days)
- Recent trauma including cardiopulmonary resuscitation
- Severe, uncontrolled arterial hypertension
- High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation
- Subacute bacterial endocarditis
- Hemostatic defects including those secondary to severe hepatic or renal disease
- Pregnancy
- Cerebrovascular disease
- Diabetic hemorrhagic retinopathy
- Prior severe allergic reaction to streptokinase
- Septic thrombophlebitis or occluded AV cannula at seriously infected site
- Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Should serious spontaneous bleeding (not controllable by local pressure) occur, the infusion of Streptase® (streptokinase) should be terminated immediately and treatment instituted as described under ADVERSE REACTIONS.

Use of Anticoagulants

Concurrent use of anticoagulants with intravenous administration of Streptase® (streptokinase) is not recommended. However, concurrent use of heparin may be required during intracoronary administration of Streptase® (streptokinase). Clinical studies with concurrent use of heparin and lower Streptase® (streptokinase) dosages employed during intracoronary administration have demonstrated no tendency toward increased bleeding that would not be attributable to the procedure or Streptase® (streptokinase) alone. Nevertheless, careful monitoring for excessive bleeding is advised.

Arrhythmias

Rapid lysis of coronary thrombi has been reported occasionally to cause reperfusion atrial or ventricular dysrhythmias requiring immediate treatment. During studies, careful monitoring for arrhythmia was maintained during and immediately following intracoronary administration of Streptase® (streptokinase).

PRECAUTIONS

Use in Pregnancy and Children

Safety and effectiveness of Streptase® (streptokinase) therapy in children and during pregnancy have not been established. Therefore, treatment of such patients is not recommended.

Drug Interactions

The interaction of Streptase® (streptokinase) with other drugs has not been studied. Drugs that alter platelet function should not be used during therapy. Common examples are: aspirin, indomethacin, and phenylbutazone.

Patient Monitoring

Before commencing thrombolytic therapy, it is desirable to obtain a thrombin time (TT), activated partial thromboplastin time (APTT), prothrombin time (PT), hematocrit and platelet count to obtain hemostatic status of the patient.

Intracoronary Artery Infusion

During studies, laboratory monitoring of hemostatic parameters during intracoronary artery infusion showed minimal changes, if any. Heparin was continued during therapy or instituted following therapy and monitored accordingly.

ADVERSE REACTIONS

The following adverse reactions have been frequently associated with intravenous therapy but may also occur with intracoronary artery infusion:

Bleeding

Minor bleeding occurs often with thrombolytic therapy mainly at invaded or disturbed sites. When lytic therapy is continued while local measures are used to control minor bleeding, do **not** reduce the dose as this will increase lytic activity since more plasminogen will be available for conversion to plasmin. Severe internal bleeding involving gastrointestinal, genitourinary, retroperitoneal or intracerebral sites, may occur. Several fatalities due to cerebral and other serious internal hemorrhage have occurred during intravenous thrombolytic therapy.

Should uncontrollable bleeding occur, Streptase® (streptokinase) infusion should be discontinued and, if necessary, blood loss and reversal of the bleeding tendency can be effectively managed with whole blood (fresh blood preferable), packed red blood cells and cryoprecipitate or fresh frozen plasma. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for streptokinase has not been documented, it may be considered in an emergency situation.

Allergic Reactions

Reactions attributed to possible anaphylaxis have been observed rarely in patients treated with Streptase® (streptokinase) intravenously. These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling or angioneurotic edema. Other milder allergic effects such as urticaria, itching, flushing, nausea, headache and musculoskeletal pain have also been observed.

Mild or moderate reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase® (streptokinase), with adrenergics, antihistamines, or corticosteroids administered intravenously as required.

Fever

Although Streptase® (streptokinase) is nonpyrogenic in standard animal tests, approximately one-third of patients treated with Streptase® (streptokinase) intravenously have shown increases in body temperature of ≥ 1.5°F. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is recommended.

DOSAGE AND ADMINISTRATION

Lysis of Coronary Artery Thrombi

During clinical studies, Streptase® (streptokinase) was administered selectively into the thrombosed coronary artery via coronary catheter placed by the Judkins or Sones Technique. When administered within 6 hours of onset of symptoms of acute transmural myocardial infarction, at a bolus dose averaging 20,000 IU and a maintenance dose averaging 2,000 IU/min for 60 minutes, greater than 75% of occlusions were opened in less than 1 hour.

How Supplied

Streptase® (streptokinase) is supplied as a lyophilized white powder in 6.5 mL vials (in packages of 10) with color-coded labels corresponding to the amount of purified Streptase® (streptokinase) in each vial as follows:

green — 250,000 IU blue — 750,000 IU

Store unopened vials at controlled room temperature (15-30°C).

CONTENTS

1301 Left Ventricular End-Systolic Stress-Shortening and Stress-Length Relations in Humans. Normal Values and Sensitivity to Inotropic State

KENNETH M. BOROW, LAURENCE H. GREEN, WILLIAM GROSSMAN, and EUGENE BRAUNWALD

The extent of left ventricular fiber shortening is determined by both the wall stress at end-systole and the contractile state. The relations between these variables were assessed in 26 normal subjects using M-mode echocardiography, phonocardiography, and indirect carotid pulse tracings during infusion of methoxamine to alter load and the infusion of dobutamine to increase contractility. End-systolic pressure was estimated from the incisura of a calibrated carotid pulse tracing. Left ventricular end-systolic dimension, wall thickness, and percent dimension change were determined by echocardiography, and end-systolic meridional wall stress was calculated. The relation between end-systolic stress and shortening was inversely linear ($r = -0.83$) and highly sensitive to inotropic state. The relation between end-systolic stress and dimension showed wider scatter ($r = 0.56$) and was less sensitive to changes in left ventricular contractility than was the stress-shortening relation.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1309 Electrophysiologic Testing in the Evaluation of Patients With Syncope of Undetermined Origin

DAVID S. HESS, FRED MORADY, and MELVIN M. SCHEINMAN

Thirty-two patients were evaluated for recurrent syncope with invasive electrophysiologic techniques after conventional neurologic and cardiovascular testing failed to demonstrate a cause. During the electrophysiologic evaluation, 11 patients were found to have laboratory-induced ventricular tachycardia, 5 had evidence of sinus nodal dysfunction, 1 had infra-His atrioventricular block during right atrial pacing, and 1 had quinidine-related ventricular tachycardia. After a mean follow-up of 21.3 ± 1.2 months, 10 of 11 patients with inducible ventricular tachycardia were asymptomatic on laboratory-directed antiarrhythmic therapy, and 5 of the remaining 7 patients with an electrophysiologic abnormality were asymptomatic after pacemaker implantation or alteration of previous drug therapy, or both. During empiric therapy, syncope recurred in 4 of the 14 patients with a normal electrophysiologic study. In patients with syncope of unknown origin, invasive electrophysiologic studies provided a presumptive cause in 56% of patients, with unsuspected ventricular tachycardia accounting for 61% (11 of 18) of the detected abnormalities.

1316 Value of the H-Q Interval in Patients With Bundle Branch Block and the Role of Prophylactic Permanent Pacing

MELVIN M. SCHEINMAN, ROBERT W. PETERS, MARY JANE SAUVÉ, JAWAHAR DESAI, JOSEPH A. ABBOTT, JOHN COGAN, BARRY WOHL, and KATHERINE WILLIAMS

His bundle electrograms were obtained in 313 patients with chronic bundle branch block who were followed up for 3 years. The infranodal conduction time (H-Q interval) was <55 ms in 97 patients (Group I), 55 to 69 ms in 99 patients (Group II), and ≥70 ms in 117 patients (Group III). Mortality and sudden death were similar among groups, but Group III had a greater incidence of progression to high degree atrioventricular block than did Groups I and II. High degree block was found in 4 of 17 patients (24%) with an H-Q interval ≥100 ms. Sixty-two patients underwent permanent prophylactic pacemaker insertion and were compared with 231 who did not. Mortality and the incidence of sudden death were similar among groups, but relief of symptoms was significantly more common in patients with pacemakers. An H-Q interval ≥100 ms identified a group at particularly high risk for high degree block, and prophylactic pacemakers relieved neurologic symptoms but did not prolong life.

1323 Effects of Verapamil on the Electrophysiologic Properties of the Accessory Pathway in Patients With the Wolff-Parkinson-White Syndrome

RICHARD W. HARPER, ERIC WHITFORD, KEN MIDDLEBROOK, JACK FEDERMAN, STAN ANDERSON, and AUBREY PITT

Intravenous verapamil increased the maximal 1:1 atrioventricular conduction through the accessory pathway during incremental high rate atrial pacing in 10 of 12 patients with symptomatic Wolff-Parkinson-White syndrome. The mean increase was 31 beats/min, and the effect of verapamil was most pronounced in patients with

Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.

patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

reduces the risk of reinfarction for many stabilized post-MI patients

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:
Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:
Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:
General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:
BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n = 176) %	Placebo (n = 168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n = 945) %	Placebo (n = 939) %	Timolol (n = 945) %	Placebo (n = 939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1

Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.
‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

relatively fast control values for this variable. In 4 patients in whom episodes of atrial fibrillation could be compared before and after verapamil, the drug decreased the average R-R interval by a mean value of 45 ms and decreased the shortest R-R interval between preexcited beats by an average of 28 ms. These findings suggest that verapamil may increase the ventricular response through the accessory pathway should spontaneous atrial fibrillation occur in patients with Wolff-Parkinson-White syndrome.

1331 Atrial Excitability and Conduction in Patients With Interatrial Conduction Defects

ROSS J. SIMPSON, Jr., JAMES R. FOSTER, and LEONARD S. GETTES

In order to better understand electrophysiologic characteristics of the atrium in patients with prolonged P-wave durations, atrial excitability and conduction times of 7 patients with P-wave durations <115 ms (Group I) were compared with those in 13 patients with P-wave durations ≥ 115 ms (Group II). In contrast to Group I patients, most patients in Group II had atrial arrhythmias, including sinus nodal dysfunction, atrial fibrillation, or ectopic atrial tachycardia. The electrophysiologic difference between the 2 groups included a higher late diastolic threshold in Group II and a greater increase in intra- and interatrial conduction times of early premature responses in Group II. There was no difference between the 2 groups in refractory periods, shape of the strength interval curve, and conduction times of premature responses occurring late in diastole. These abnormalities of atrial conduction time and excitability may predispose patients with prolonged P waves to atrial tachyarrhythmias.

1338 Termination of Ventricular Tachycardia. Evaluation of a New Pacing Method

MARTIN J. GARDNER, HARVEY L. WAXMAN, ALFRED E. BUXTON, MICHAEL E. CAIN, and MARK E. JOSEPHSON

The efficacy of a combination method of overdrive ventricular pacing plus premature ventricular stimulation to terminate ventricular tachycardia was assessed in 25 patients in whom ventricular extrastimuli and rapid ventricular pacing at comparable cycle lengths and coupling intervals were unsuccessful. The combination method terminated ventricular tachycardia in 6 of 8 patients receiving no drugs in whom extrastimuli or pacing individually were ineffective, and in 6 of 8 patients unresponsive to extrastimuli in whom rapid pacing produced acceleration, and in 9 of 9 patients in whom antiarrhythmic agents made ventricular tachycardia unresponsive to extrastimuli and rapid pacing. The combination method of rapid pacing and extrastimuli appears useful in terminating tachycardias unresponsive to extrastimuli or rapid pacing alone and may avoid acceleration by these methods in certain patients.

1346 Termination of Ventricular Tachycardia: Role of Tachycardia Cycle Length

DENIS ROY, HARVEY L. WAXMAN, ALFRED E. BUXTON, FRANCIS E. MARCHLINSKI, MICHAEL E. CAIN, MARTIN J. GARDNER, and MARK E. JOSEPHSON

The mode of termination of ventricular tachycardia and its relation to tachycardia cycle length was evaluated in 139 patients. Progressively more stimuli were required to terminate tachycardias as the cycle length decreased. Rapid pacing was the most successful method of terminating tachycardia and was the sole method of terminating tachycardias with a cycle length <300 ms. Although procainamide slows tachycardia cycle length, it may have no effect on the ability to terminate, facilitate termination, or make termination of the tachycardia more difficult. Thus, timed extrastimuli are only successful in terminating relatively slow tachycardias, rapid pacing is required for most tachycardias with cycle lengths of less than 300 ms, and procainamide unpredictably affects the ability to terminate tachycardias.

CONGENITAL HEART DISEASE

1351 Two-Dimensional Echocardiographic Assessment of Dextrocardia: A Segmental Approach

JAMES C. HUHTA, DONALD J. HAGLER, JAMES B. SEWARD, ABDUL J. TAJIK, PAUL R. JULSRUD, and DONALD G. RITTER

A segmental analysis of the atrial-visceral situs connection, ventricular anatomy, and chamber position was utilized for the complete diagnostic assessment in the 2-dimensional echocardiographic examination of 40 patients with the clinical diagnosis of dextrocardia. The echocardiographic findings were confirmed by cardiac catheterization and angiography in 31 cases and at surgery in 26 cases. By use of the location of the liver and drainage of the hepatic veins and inferior vena cava, the atrial-visceral situs was defined in all cases. Pulmonary venous connections were correctly identified in 27 cases. Atrioventricular and ventriculoarterial connections and ventricular anatomy were correctly predicted in 33 cases. Two-dimensional echocardiography allowed the accurate assessment of complex congenital heart defects associated with dextrocardia. Utilizing a segmental approach, one can correctly predict the atrial-visceral situs, ventricular morphology and situs, and atrioventricular and ventriculoarterial connections.

1361 Conotruncal Malformations: Diagnosis in Infancy Using Subxiphoid 2-Dimensional Echocardiography

STEPHEN P. SANDERS, FREDRICK Z. BIERMAN, and ROBERTA G. WILLIAMS

Subxiphoid 2-dimensional echocardiography was prospectively evaluated as a method for diagnosing conotruncal malformations in infants. One hundred four of 109 patients successfully examined were diagnosed correctly, including 46 of 46 patients with d-transposition, 10 of 11 patients with double outlet right ventricle, 34 of 36 patients with tetralogy of Fallot, 8 of 9 patients with tetralogy of Fallot and pulmonary atresia, and 5 of 6 patients with truncus arteriosus communis. Subxiphoid 2-dimensional echocardiography is a sensitive and specific method for diagnosing conotruncal abnormalities in infants.

1368 Two-Dimensional Echocardiographic Assessment of Right Ventricular Volume in Children With Congenital Heart Disease

SATOSHI HIRAISHI, THOMAS G. DiSESSA, JAY M. JARMAKANI, TOSHIO NAKANISHI, JOSEPHINE B. ISABEL-JONES, and WILLIAM F. FRIEDMAN, *With the technical assistance of* BARBARA STERNLIGHT

The ability of 2-dimensional echocardiography to measure right ventricular volume and ejection fraction was assessed in children with congenital heart disease. The area and long-axis length of the right ventricle were obtained from the apical 4-chamber echocardiographic image. The longest length, inflow tract length, and area of the right ventricular sinus were measured from the anteroposterior and lateral planes of the cineangiocardiogram. The echographic long-axis length and area were corrected to the angiographic longest length and area of the sinus. The new corrected echographic longest length and corrected echographic area were applied to 3 area-length formulas to calculate the sinus volume of the right ventricle. Total right ventricular volume was then derived from the sinus volume. All formulas tested predicted right ventricular volumes and ejection fraction well and with equal accuracy.

1376 Two-Dimensional Echocardiographic Evaluation of Persistent Truncus Arteriosus

JOSÉ MARÍN-GARCÍA and INA L. D. TONKIN

M-mode echocardiographic diagnosis of persistent truncus arteriosus is based on the presence of a large arterial trunk overriding the interventricular septum and an inability to image the pulmonary valve. These features, however, do not differentiate this anomaly from cases of tetralogy of Fallot nor from cases with pulmonary valve atresia and ventricular septal defect. Three patients aged 1 to 12 months were studied with a phased-array, wide-angle sector-scanner. Using a combination of short-axis views at the cardiac base and parasternal long-axis views, the truncus arteriosus and the pattern of pulmonary arteries were demonstrated. Type I was found in 2 patients and type II in 1. Examination from the standard planes demonstrated in each case a dilated truncal valve overriding the ventricular septal defect and absence of right ventricular outflow tract. Two-dimensional echocardiography permits accurate diagnosis of persistent truncus arteriosus.

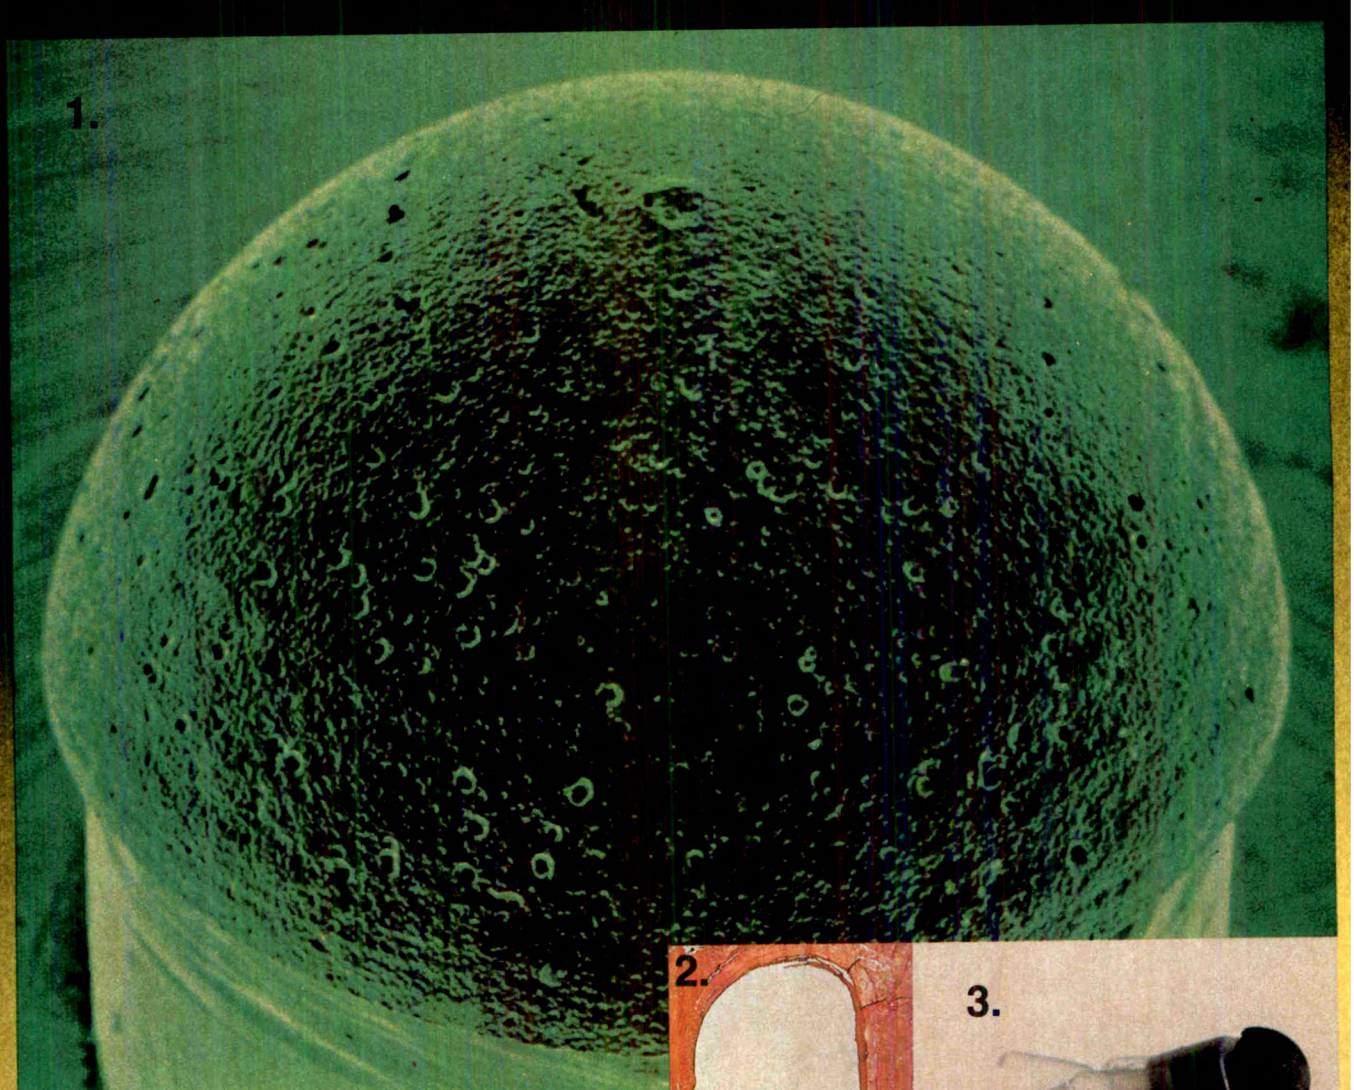
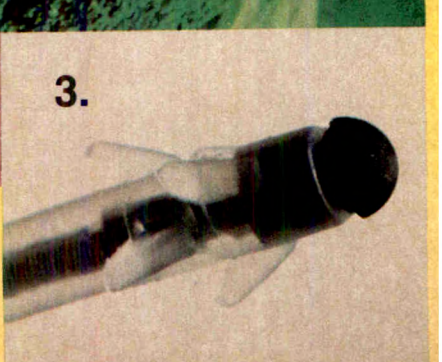
We are convinced... that carbon is far more





1. The surface structure of the vitreous carbon tip.
2. The thin fibrotic capsule formed by a carbon tip.
3. The 412S with tines for secure anchorage in the right auricle or in the ventricle.

precious than platinum.

The Siemens-Elema ACE™ (**A**ctivated **C**arbon **E**lectrode) carbon tip pacing leads utilize the unique properties of vitreous carbon.

We are the sole manufacturer of this material which, thanks to minor tissue reaction, gives significantly low polarization voltages.

Clinical experience has shown low chronic thresholds, which reduce the risk of exit block.

Pacemaker longevity can be increased through reduction of output energy, consistent with the reduced threshold of the ACE™ electrode.

82216

CAUTION:
Read Physicians Product Manual (ME 372/5713.406) for proper implantation procedures and possible complications.

POSSIBLE COMPLICATIONS
An implanted pacemaker electrode is in direct contact with the myocardium. Equipment operating on alternating current can present a risk of causing fibrillation, if it is not satisfactorily grounded, or if it is faulty. Even battery-operated instruments connected to the electrode can be dangerous, if they are in contact with the above-mentioned equipment.
The following are examples of other complications that can arise:
- Intermittent or continuous "exit block", or detection problems, caused, for example, by dislodgement of the tip of the electrode, perforation of the myocardium, or insulation defects.
- Infection at the point of connection to the vein, which can require surgical treatment.

CONTENTS

1380 Two-Dimensional Echocardiographic Prospective Diagnosis of Common Truncus Arteriosus in Infants

THOMAS W. RIGGS and MILTON H. PAUL, *With the technical assistance of* SUE PAJCIC

Two-dimensional echocardiographic prospective diagnosis of truncus arteriosus was made in 7 infants. Two infants had truncus arteriosus type I and 3 had type II, one infant had truncal valve stenosis with an interrupted aortic arch, and 1 had type IV truncus arteriosus with pulmonary hypertension. These images were contrasted with those of an infant with an aorticopulmonary window and intact ventricular septum. Although cardiac catheterization and angiography may be required to assess pulmonary artery pressure, pulmonary vascular resistance, and the distal pulmonary arterial anatomy in truncus arteriosus, 2-dimensional echocardiography can be used to correctly establish the morphologic diagnosis of truncus arteriosus in infants.

1385 Two-Dimensional Echocardiographic Features of Interruption of the Aortic Arch

THOMAS W. RIGGS, TERESA E. BERRY, KALIM U. AZIZ, and MILTON H. PAUL

Two-dimensional echocardiographic features of interruption of the aortic arch are presented based on analysis of the echocardiograms and angiograms from 8 infants. Two infants had type A interruption and 6 had type B. Six infants had a conoventricular septal defect with leftward deviation of the conal septum. The echocardiographic images were compared with those from infants with aortic artesia and hypoplastic ascending aorta or discrete coarctation of the aorta with tubular hypoplasia of the aortic arch. Types A and B were easily discriminated and the caliber of the patent ductus arteriosus was assessed. Subsequent angiography can be more expeditiously performed in this group of critically ill infants.

METHODS

1391 A Simple Teaching Device for Examination of the Arterial and Venous Pulse

ARTHUR KREITENBURG, JOEL S. KARLINER, ROBERT L. ENGLER, and E. ROGER MARCHAND

A simple teaching device for examination of the cervical arterial and venous pulses is described. It is a mechanical device which simultaneously generates a visible jugular venous pulsation and a palpable carotid arterial pulsation to train medical students, physicians, and paramedical personnel. Changing of cams allows the observer to appreciate these pulsations in the normal or a variety of abnormal states. Graphic tracings of wave forms demonstrate the accuracy of reproduction of physiologic tracings. In a test of the device, cardiologists performed significantly better than medical students in the identification of unknown pulsations. The instrument is readily accepted, simple to operate, and fully portable.

1394 Evaluation of Pulmonary and Systemic Blood Flow by 2-Dimensional Doppler Echocardiography Using Fast Fourier Transform Spectral Analysis

STANLEY J. GOLDBERG, DAVID J. SAHN, HUGH D. ALLEN, LILLIAM M. VALDES-CRUZ, HEINZ HOENECKE, and YVONNE CARNAHAN

In this study range-gated Doppler echocardiographic aortic and pulmonary outputs were compared with outputs measured simultaneously by indicator dilution. The results indicate that Doppler-measured aortic flow correlated strongly ($r = +0.94$) with indicator dilution measured output, but Doppler-measured pulmonary flow had a much weaker correlation ($r = +0.72$) with indicator dilution-measured flow. The major difficulty encountered with the Doppler flow technique was echocardiographic determination of great vessel diameter, particularly for the pulmonary artery. If angiographic pulmonary artery diameter was substituted for echocardiographic vessel measurement, the correlation of Doppler and invasive pulmonary flow measurement increased to $r = +0.94$. Other problems encountered with measurement of Doppler flow included encountering turbulence and inability to measure the Doppler beam flow intercept angle simultaneously in 3 axes. Nonetheless, Doppler measurement of aortic and pulmonary flow is clinically practical and accurate if precautions are observed.

Choice of citrus or fruit-punch flavors

K-LYTE/CL®

Each effervescent tablet in solution supplies 25 mEq potassium chloride

It's everything you need in a potassium supplement.

Mead Johnson PHARMACEUTICAL DIVISION

Double-strength K-Lyte/Cl® 50 also available. Each effervescent tablet in solution supplies 50 mEq potassium chloride.

© 1982 Mead Johnson & Company • Evansville, Indiana 47721 USA

Please see following page for summary of prescribing information.

K-Lyte/Cl® 50 (Each effervescent tablet in solution supplies 50 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)
K-Lyte/Cl® (Each effervescent tablet in solution supplies 25 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)

Description: K-Lyte/Cl 50 and K-Lyte/Cl are oral potassium and chloride supplements. Each K-Lyte/Cl 50 mEq tablet in solution provides 50 mEq of potassium and chloride as supplied by 2.24 gm of potassium chlorice, 2.0 gm of potassium bicarbonate, and 3.65 gm of L-lysine monohydrochloride with 1.0 gm of citric acid, saccharin, natural and artificial flavor and artificial color. Each K-Lyte/Cl tablet in solution provides 25 mEq of potassium and chloride as supplied by 1.5 gm of potassium chloride, 0.5 gm of potassium bicarbonate and 0.91 gm of L-lysine monohydrochloride with 0.55 gm of citric acid, saccharin, natural and artificial flavor and artificial color.

Indications and Usage: All K-Lyte® products are used for therapy or prophylaxis of potassium deficiency. They are useful when thiazide diuretics, corticosteroids, or diarrhea cause excessive potassium loss: and when dietary potassium is low. These products may also be useful when potassium therapy is indicated in digitalis intoxication. K-Lyte/Cl 50 and K-Lyte/Cl are recommended in the management of hypokalemia accompanied by metabolic alkalosis and hypochloremia, e.g., as induced by vomiting.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions; chronic renal impairment, metabolic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns or adrenal insufficiency. Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Warnings: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Precautions: *General precautions* – The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. When interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Therefore, the treatment of potassium depletion requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the ECG, and the clinical status of the patient.

Information for patients – To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each dose completely in the stated amount of water.

Laboratory tests – Frequent clinical evaluation of the patient should include ECG and serum potassium determinations.

Drug interactions – The simultaneous administration of potassium supplements and a potassium-sparing diuretic can produce severe hyperkalemia (see Contraindications). Potassium supplements should be used cautiously in patients who are using salt substitutes because most of the latter contain substantial amounts of potassium. Such concomitant use could result in hyperkalemia.

Usage in pregnancy – Pregnancy Category C – Animal reproduction studies have not been conducted with any of the K-Lyte products. It is also not known whether these products can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. They should be given to a pregnant woman only if clearly needed.

Nursing mothers – Many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from oral potassium supplements, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

Usage in children – Safety and effectiveness in children have not been established.

Adverse Reactions: The most common adverse reactions to oral potassium supplements are nausea, vomiting, diarrhea and abdominal discomfort. These side effects occur most frequently when the medication is not taken with food or is not diluted properly or dissolved completely.

Hyperkalemia occurs only rarely in patients with normal renal function receiving potassium supplements orally. Signs and symptoms of hyperkalemia are cardiac arrhythmias, mental confusion, unexplained anxiety, numbness or tingling in hands, feet or lips, shortness of breath or difficult breathing, unusual tiredness or weakness and weakness or heaviness of legs (see Contraindications, Warnings and Overdosage).

Dosage and Administration: *Adults* – One (1) K-Lyte/Cl 50 tablet (50 mEq potassium and chloride) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily, depending on the requirements of the patient. One (1) K-Lyte/Cl tablet (25 mEq potassium and chloride) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily, depending on the requirements of the patient.

Note: It is suggested that all K-Lyte products be taken with meals and sipped slowly over a 5 to 10 minute period.

How Supplied: K-Lyte/Cl® Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30, 100 and 250. K-Lyte®/Cl 50 Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30 and 100. Each tablet is individually foil wrapped.

CARDIOLOGIST Board certified/eligible C.V. disease. Must have or be eligible for Nuclear license to join two man group in very active practice of invasive and non-invasive cardiology, including post-operative open heart care in north east metropolitan area. Initial salary, excellent benefits. Later partnership possible. Reply to Box 240, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

HOUSTON—POSITION AVAILABLE FOR BOARD CERTIFIED OR ELIGIBLE CARDIOLOGIST. Accredited 67-physician internal medicine group. For further information, send Curriculum Vitae to Administrator, Diagnostic Clinic of Houston, 6448 Fannin, Houston, Texas 77030.

CARDIOLOGIST

wanted to join three man cardiology-internal medicine group in Piedmont North Carolina. Please send curriculum vitae and references to Box 245, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CARDIOLOGIST-ELECTROPHYSIOLOGIST. The Marshfield Clinic is seeking a board certified/eligible cardiologist with extensive training and experience in electrophysiology and all aspects of arrhythmia evaluation and management. This individual will complement an existing eight member Department of Cardiology in a large multispecialty clinic. Send CV to W. Bruce Fye, M.D.; Chairman, Department of Cardiology; Marshfield Clinic; Marshfield, Wisconsin, 54449.

PROFESSIONAL RESUME SERVICES, 1125 SOUTH CEDAR CREST BOULEVARD, ALLENTOWN, PENNSYLVANIA 18103. CV PREPARATION FOR PHYSICIANS. PROMPT. CONFIDENTIAL. CALL OR WRITE FOR INFORMATION. (215) 433-4112.

CARDIOLOGIST

Board eligible or certified to share a hospital based practice with two other cardiologists. Our new associate will join a growing practice involving invasive and non-invasive cardiology, consulting, and work in a newly constructed C.C.U. The successful candidate will practice at a progressive mid-western hospital affiliated with a state school of medicine. Please reply with curriculum vitae to: Box 230, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

CONTENTS

1401 The Isovolumic Index: A New Noninvasive Approach to the Assessment of Left Ventricular Function in Man

G. B. JOHN MANCINI, DENNIS COSTELLO, VALMIK BHARGAVA, WILBUR LEW, MARTIN LeWINTER, and JOEL S. KARLINER

In this study, the ability of a new, noninvasive, combined isovolumic index to detect abnormal left ventricular function in human subjects was tested. The isovolumic index was defined as the sum of isovolumic contraction and relaxation times divided by the left ventricular ejection time $\times 100\%$, and was derived from simultaneous electrocardiographic, indirect carotid arterial pulse, and M-mode echocardiographic anterior mitral leaflet recordings. Normal subjects had a value of $24 \pm 7\%$ (standard deviation), in contrast to patients with cardiomyopathy ($65 \pm 14\%$, $p < 0.001$) and a diverse group of patients with coronary artery disease ($40 \pm 15\%$, $p < 0.001$). An abnormal isovolumic index was highly sensitive for identifying patients with coronary artery disease with a reduced ejection fraction or segmental wall motion disorder and was also superior to both abnormal E point-septal separation and the PEP/LVET ratio in detecting abnormal left ventricular function. The isovolumic index is thus a potentially useful and easily obtainable noninvasive marker of left ventricular dysfunction.

EXPERIMENTAL STUDIES

1409 Exercise-Induced Decrease in Flow Through Stenotic Coronary Arteries in the Dog

JEFFREY S. SCHWARTZ, BRUCE TOCKMAN, JAY N. COHN, and ROBERT J. BACHE

In the presence of a coronary stenosis, it is generally believed that exercise-induced ischemia is due to an inadequate increase in coronary blood flow. This study evaluated the hypothesis that exercise may cause a decrease in flow across a severe compliant coronary stenosis. Five unsedated, chronically instrumented dogs were studied. In the presence of a severe circumflex coronary stenosis produced with a snare, exercise caused an increase in heart rate, no significant change in mean aortic pressure, a decrease in pressure distal to the stenosis, an increase in stenosis resistance and a decrease in circumflex blood flow. The decrease in intraluminal pressure distal to the stenosis and thus in the stenosis itself may have resulted in passive narrowing of the stenotic segment, which may have caused the decrease in flow. Exercise, therefore, may produce a decrease in flow through a stenotic coronary artery.

1414 Ventricular Fibrillation Resulting From Ischemia at a Site Remote From Previous Myocardial Infarction. A Conscious Canine Model of Sudden Coronary Death

EUGENE PATTERSON, KURT HOLLAND, BRIAN T. ELLER, and BENEDICT R. LUCCHESI

These studies describe a conscious canine model in which a previous myocardial infarction renders the animal susceptible to the development of ventricular tachycardia in response to programmed electrical stimulation. The subsequent superimposition of regional ischemia at a site remote from the area of previous myocardial injury is accompanied by the development of continuous diastolic electrical activity, ventricular tachycardia, and the sudden onset of ventricular fibrillation. The model affords the opportunity to study electrophysiologic mechanisms leading to the onset of lethal dysrhythmias and to initiate studies aimed at identifying antifibrillatory agents intended for the prevention of sudden coronary death in man.

1424 Quantitative Assessment of Infarct Size Reduction by Coronary Venous Retroperfusion in Baboons

GRAYSON G. GEARY, GREGORY T. SMITH, GLEN T. SUEHIRO, CHARLES ZEMAN, BENJAMIN SIU, and J. JUDSON McNAMARA

The effectiveness of coronary venous retroperfusion to reduce infarct size was evaluated with use of an accurate quantitative method in which infarct size was related to the size of the anatomic perfusion bed of the occluded artery (region at risk for infarction). In an experimental group of 5 baboons, the left anterior descending coronary artery was occluded and coronary venous retroperfusion initiated 1 hour after occlusion. After a 4-hour period of occlusion, retroperfusion was discontinued and anterograde perfusion was simultaneously restored. A control group of 5 baboons underwent an identical procedure without retroperfusion. The perfusion bed of the previously occluded coronary artery was delineated by injection of microvascular dye. The mean percentage of the perfusion bed infarcted was 94.1 ± 0.9 (mean $\pm$ standard error) in the control group and 57.4 ± 3.5 in the retroperfusion group ($p < 0.001$). Hence, retroperfusion initiated after 1 hour of coronary occlusion and maintained for a 4-hour period of occlusion resulted in substantial salvage of ischemic myocardium.

CORONARY HEART DISEASE

Effects of Carbon Dioxide, Nd-YAG, and Argon Laser Radiation on Coronary Atheromatous Plaques

GEORGE S. ABELA, MD, SIGURD NORMANN, MD, PhD, DONALD COHEN, BS, ROBERT L. FELDMAN, MD, EDWARD A. GEISER, MD, and C. RICHARD CONTI, MD

Laser radiation has been successfully applied in several areas of medical practice. However, its use in cardiology and specifically its effects on obstructive atherosclerosis have largely been unexplored. To evaluate effects of laser radiation on atherosclerotic plaques 25 fresh necropsy atherosclerotic coronary artery segments were exposed to laser radiation with either a carbon dioxide, Nd-YAG, or argon laser. Split or intact segments were prepared under dry conditions or while immersed in saline solution or blood and exposed to laser radiation as power and duration of exposure varied. All 3 lasers were capable of creating controlled injury to atherosclerotic plaques. In general, the magnitude of injury varied according to the total energy delivered (that is, power times duration of exposure). Calcified and noncalcified plaques were penetrated with similar levels of injury. Histologic examination demonstrated that laser radiation produced a wedge incision in the atherosclerotic plaque which was surrounded by zones of thermal and acoustic injury.

Currently, 2 nonsurgical techniques are used to recanalize partly or totally occluded arteries: percutaneous transluminal angioplasty,[1-3] and systemic or regional thrombolytic therapy.[4,5] Laser radiation may offer a third technique to improve perfusion through obstructed arteries.

Laser radiation is a monochromatic and coherent light that can be carried by optical fibers. It has found selected medical uses including destruction of hemangiomas and other cutaneous lesions,[6] hemostasis at the site of bleeding ulcers,[7] and photocoagulation for retinal neovascularization.[8] Recent attempts to anastamose arterial segments with laser radiation have also been successful.[9] Pulmonary stenosis in dogs has partly been relieved using a laser to create holes in the pulmonary valve cusps.[10] Preliminary studies have demonstrated the feasibility of lasers in vitro to damage atheromatous plaques.[11-13] The effects of laser radiation on atherosclerotic plaques, however, have not been extensively described. In this report we describe gross and histologic effects of laser radiation on atherosclerotic plaques under wet (saline solution and blood) and dry conditions using fresh human necropsy coronary arteries.

Methods

Human coronary arteries were obtained from 15 patients within 24 hours of death. The coronary arteries were dissected from the heart, partitioned into 2 to 5 cm segments and flushed with normal saline solution to remove blood and loose

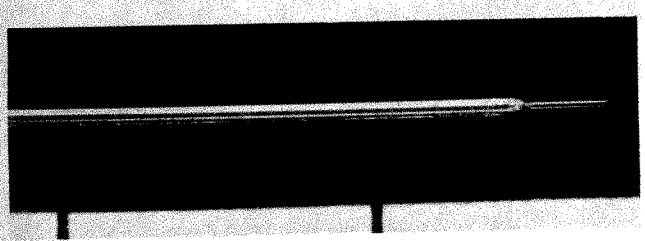

FIGURE 1. Silica fiber used to transmit laser light. The fiber is composed of multiple layers. These are, from inner to outer layer, a silica core surrounded by a silica envelope, a polymer buffer, and finally a Teflon® coating. The distance between the 2 black markers is 1 cm.

debris; 25 segments were selected for study based on atherosclerotic involvement. There were 11 segments of the left anterior descending coronary artery and 7 each from the left circumflex and the right coronary arteries. Experiments were begun within 30 minutes of isolating the coronary artery.

Carbon dioxide laser: Eleven coronary artery segments were split longitudinally, exposing the lumen. Eight split segments were used under dry conditions, and 3 others were placed in a petri dish and immersed in normal saline solution. Atherosclerotic plaques were exposed to carbon dioxide (CO_2) laser radiation (wavelength 10,600 nm) from a Sharplan model 733 laser source (Tel Aviv, Israel). The focal spot size was 0.2 mm. Multiple exposures were made on each coronary artery segment varying the duration of exposure (0.1, 0.2, or 0.5 second) and the amount of power (2, 5, 10, 15, 20, 25, or 30 W).

Nd-YAG and argon lasers: An Nd-YAG (neodymium-yttrium, aluminum, garnet) laser with a wavelength of 1,064 nm (model 510, Control Laser of Orlando, Florida) and Argon laser (model 554A Laser Ionics, Orlando, Florida) with wavelengths of 488 and 514 nm were also evaluated. These lasers were coupled to a fiberoptic system consisting of a 0.5 mm diameter silica fiber (Medicore Optical Fiber Med 200, Quartz Products, Plainfield, New Jersey), which was polished smooth at both ends and 80 to 100 cm long (Fig. 1). One end was aligned with the focused laser beam as it exited from the laser, and the free end was used for lasing. The power reading on the laser meter did not represent the actual power delivered at the fiber tip because of attenuation over the length of the silica fiber. To measure the actual power at the fiber tip, a power meter (Coherent model 105 Power Meter, Palo Alto, California) was positioned adjacent to the tip of the free end of the fiber and the power range of each laser examined. Only the power measured at the tip will be reported.

Seven intact coronary artery segments, chosen because of multiple areas of totally occlusive atherosclerosis, were used to evaluate effects of Nd-YAG laser radiation during immersion in normal saline solution. The occluded portion of the segments ranged from 5 to 10 mm long. In 2 segments 6 separate regions were lased after staining with cardiogreen or Sudan black. Before lasing, excess dye was removed by washing the segments in saline solution. Under the direct vision, the free end of the optical fiber was placed in line with the coronary artery lumen and against the atherosclerotic plaque. It was necessary for the fiber tip to be touching the plaque as the power density (W/cm^2) delivered decreased markedly as distance from the tip increased beyond 1 mm. The power at the tip was varied between 1.2 and 9 W. The laser was used in continuous wave mode. Every 5 to 10 seconds the magnitude of plaque injury was visually assessed, the laser position was adjusted if necessary, and lasing was continued until the plaque was penetrated or the artery perforated. In many experiments, several new lumens were lased in an occluded coronary artery segment. The effect of the Nd-YAG laser also was evaluated in a similar fashion in 5 intact arterial segments immersed in citrated whole blood. The Argon laser was tested in a similar fashion as the Nd-YAG laser. Two arterial segments were used, 1 immersed in saline solution and the other in blood.

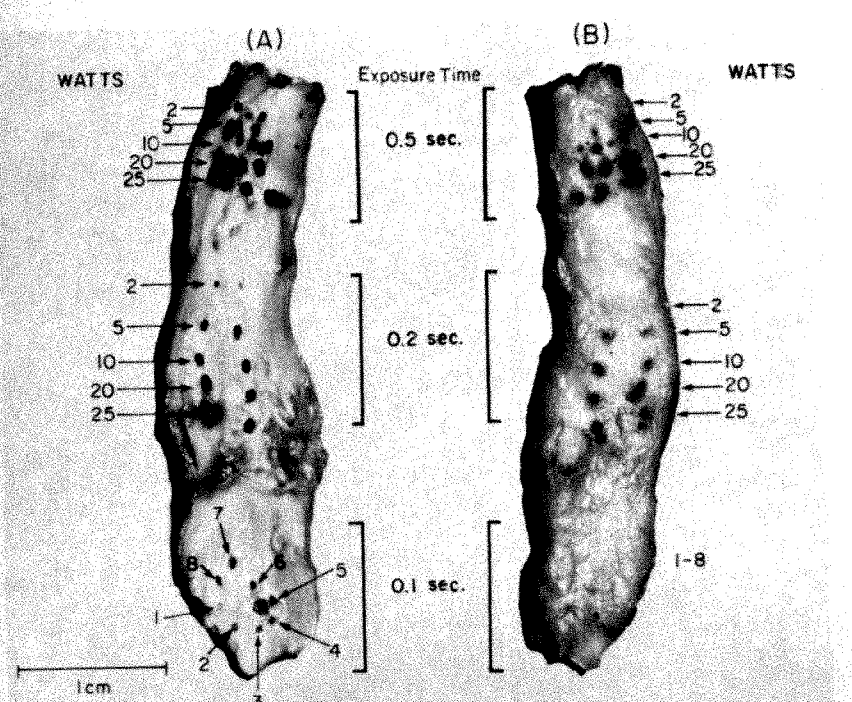

FIGURE 2. Example of increasing plaque damage from a split coronary artery segment as the total energy of exposure was increased (CO_2 laser under dry conditions). Multiple exposures were made at progressively higher power (watts) and longer duration (seconds). **A,** the lumen side of an anterior descending artery. As total energy increased first crater depth and diameter increased and then perforation occurred. **B,** the serosal side of the same artery showing perforation with increased energy.

Histology: After exposure to laser radiation, all tissue samples were fixed in 10% neutral buffered formalin and embedded in paraffin. Tissue blocks were cut in sections of 4 μm thickness. Sections from each tissue block were stained with hematoxylin and eosin. Ten sections were stained with either Masson's trichrome or with Verhoff-Van Gieson's stain. Each section was evaluated by light microscopy at a range of magnifications from 25 to 120×.

Calculations and definitions: In intact occluded coronary artery segments lasing was considered successful if the plaque was penetrated and a new lumen established. Perforation was defined as rupture through the entire thickness of the arterial wall. Total energy delivered in joules was calculated as the product of amount of power (watts) and duration of exposure (seconds).

Results

Effects of exposure to carbon dioxide laser radiation under dry conditions: Over 100 applications of carbon dioxide laser radiation were made under dry conditions; an example of 1 segment is shown in Figure 2. Increasing duration of exposure at a constant power produced an injury similar to that of increasing power at a constant duration of exposure. When total energy was 1 to 2 J, the plaque was penetrated. Between 2.5 and 5 J, both the plaque and the media were penetrated. With exposure >7.5 J, the vessel was consistently perforated.

Histologic examination was done in 108 sections. As observed by inspection of the gross specimen, crater diameter and depth were directly related to total energy applied. Three zones of tissue injury in the atheroma and surrounding vessel wall were observed (Fig. 3 to 5). Zone 1 consisted of a crater that was the result of tissue vaporization. The vaporization of tissue was complete, as no debris remained. Zone 2 consisted of a region of thermal-induced necrosis and coagulation. It consisted of a narrow band of tissue charring and then a region of tissue coagulation that varied between 5 and 15 μm in diameter. Zone 3 comprised a distal and diffuse region of acoustic or shock injury. This region could extend up to 30 μm from the edge of zone 1. It gradually faded into

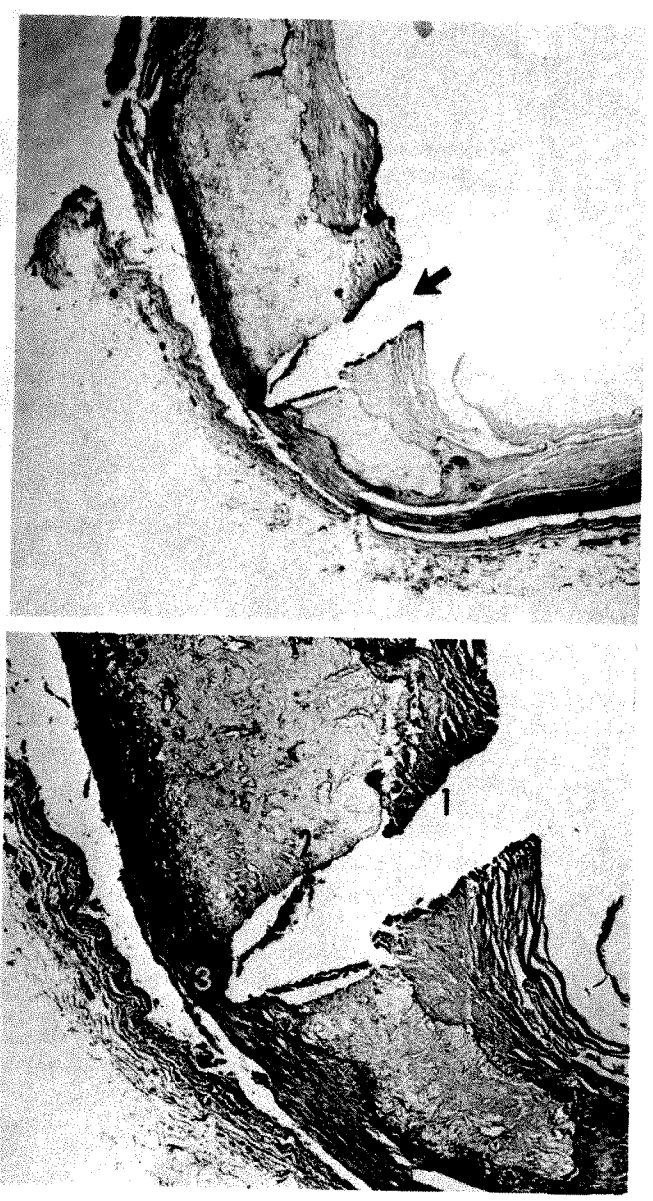

FIGURE 3. Histology of a laser injury to a fatty atherosclerotic plaque. The vessel was exposed to 5 J of total energy from a CO_2 laser under dry conditions. **Top,** low-power view (52×) of an atheroma showing a wedge-shaped incision (**arrow**). **Bottom,** higher magnification (119×) of the same artery showing the laser incision (1) and complete penetration of the fatty atheromatous core (2). The media has also been partly penetrated (3). Note the zone of complete vaporization of tissue and the zone of tissue burn along the laser path. (Hemotoxylin and eosin stain; reduced 30%.)

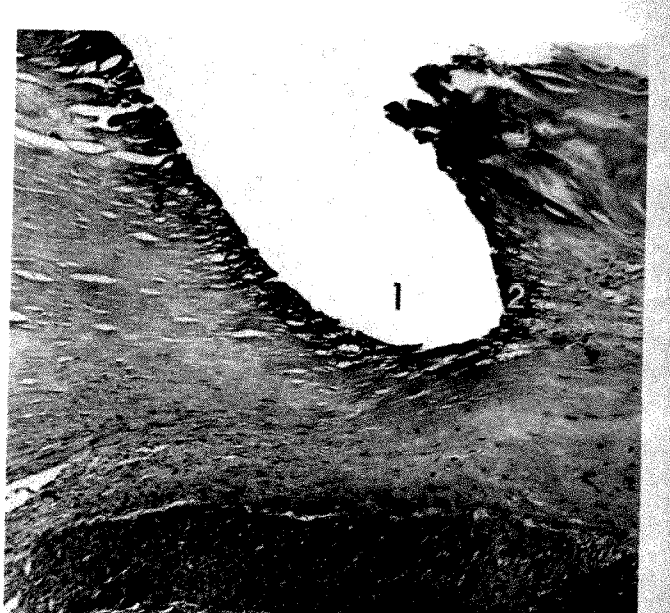

FIGURE 4. Histology of a laser injury to a fibrous atherosclerotic plaque. The vessel was exposed to 2 J of energy from a CO_2 laser under dry conditions. This section shows a zone of tissue vaporization in the path of the laser (1), a zone of adjacent tissue burn (2), and a zone of acoustic shock and injury that begins at the tissue burn edge and fades gradually into normal tissue structure (3). (Hematoxylin and eosin stain; magnified ×112, reduced 33%.)

FIGURE 5. Histology of a laser injury to a calcified fibrous atherosclerotic plaque. The vessel was exposed to 2 J of energy from a CO_2 laser under dry conditions. The calcified portion of the plaque is the area with more basophilic staining. The laser has penetrated the overlying fibrous tissue and has vaporized a portion of the calcified atheroma (**arrow**). (Hematoxylin and eosin stain; magnified ×67, reduced 33%.)

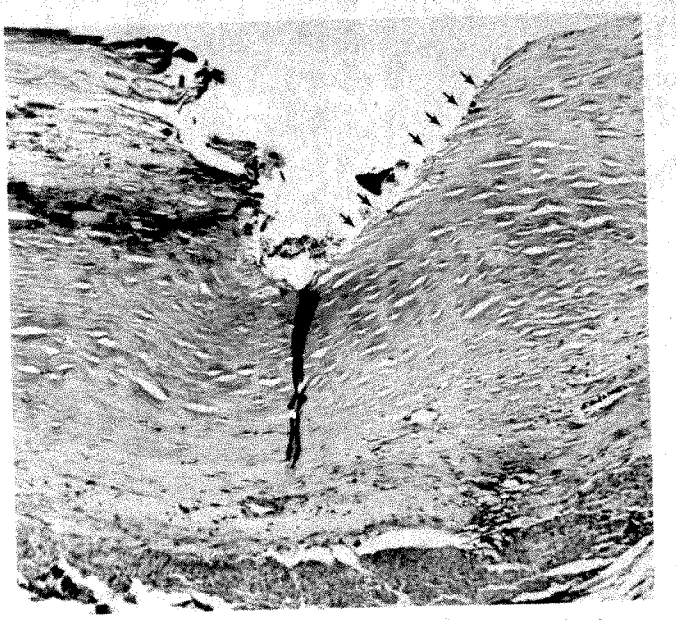

FIGURE 6. Histology of laser injury to a fibrous atherosclerotic plaque. The vessel was immersed in saline solution and exposed to 10 J of energy from a CO_2 laser. The incision penetrates the capsule and a portion of the fibromuscular atheroma. Note the absence of charring along the laser path (**arrows**). These effects differ from those when a plaque was lased under dry conditions (see Fig. 2 to 5). (Hematoxylin and eosin stain; magnified ×112, reduced 33%.)

undisturbed tissue and its precise outer border was difficult to define. Although the size of Zone 1 increased with applied energy, the surrounding zones of tissue injury appeared relatively constant in size. In addition, the histologic type of atherosclerotic plaque and the presence or absence of calcium did not appear to affect the magnitude of laser injury.

Effects of exposure to carbon dioxide laser radiation under saline solution: Twenty exposures were made and 30 tissue sections examined. Two important differences were noted between lasing under dry conditions and while immersed in saline solution. First, when immersed in saline solution more total energy was required to penetrate the plaque than was required under dry conditions. Arterial perforation could not be achieved even with the maximal power of 30 W and an exposure time of 0.5 second (15 J). With this amount of energy, only the plaque and underlying media were penetrated. This was approximately twice the energy required to perforate the artery under dry conditions. Second, microscopic examination of arterial segments

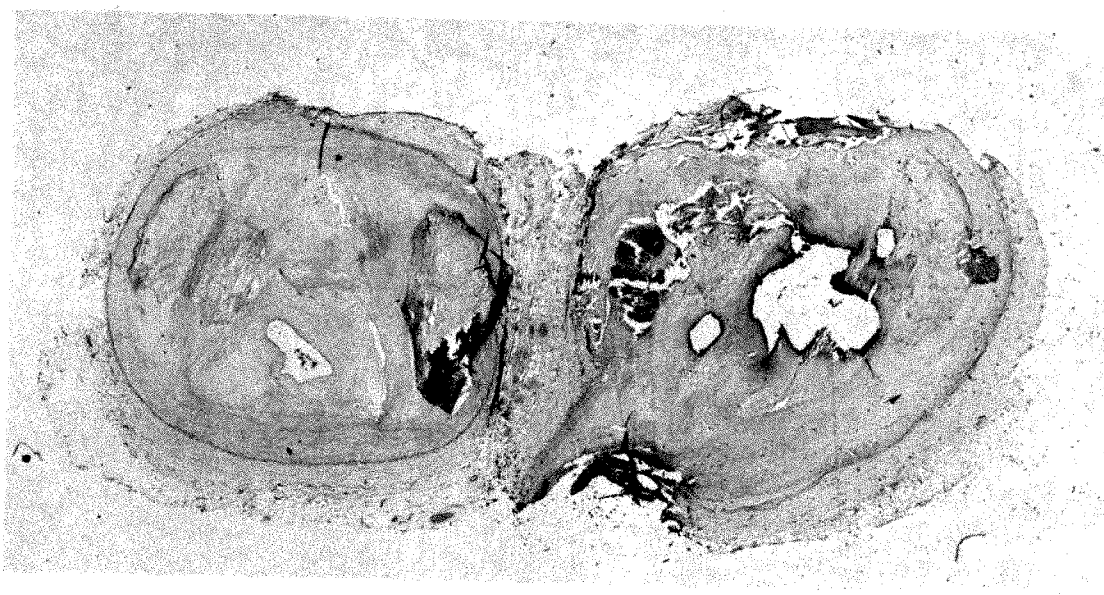

FIGURE 7. Establishment of a new lumen by exposure to Nd-YAG laser radiation in an occluded coronary artery immersed in saline solution. The artery was exposed to 71 J of energy. The artery was cut in half and the portion not exposed to laser radiation was used for comparison. A cross-section of the portion not exposed to laser radiation is shown on the **left** and of the portion exposed to laser radiation on the **right**. (Magnification ×25.)

exposed under saline solution revealed little to no charring along the incision edge of the laser (Fig. 6). When immersed in saline solution, small bubbles were produced during lasing.

Effects of exposure to Nd-YAG laser radiation under saline solution (Table I): Gross inspection of the occluded coronary artery segment exposed to Nd-YAG laser radiation demonstrated that the plaque was damaged but not penetrated when the total energy of exposure was less than 45 J. Between 55 and 90 J, successful plaque penetration occurred but without perforation (Fig. 7). Energy levels greater than 144 J consistently perforated. Because the energy required for plaque penetration was similar in plaques stained with cardiogreen, this dye did not enhance laser absorption. In contrast, staining with Sudan black did enhance laser absorption as the energy needed for successful plaque penetration decreased. Forty histologic sections were examined. Findings were similar to that described for the carbon dioxide laser when segments were immersed

in saline solution. When Sudan black was used the amount of superficial tissue injury usually seemed greater (Fig. 8). Small bubbles were noted at the fiber tip during lasing.

Effect of exposure to Nd-YAG laser radiation under blood (Table II): In general, when immersed in blood, less total energy was required to successfully penetrate an atherosclerotic plaque as compared with immersion in saline solution. Two exposures were made at a much lower power (1.2 and 1.9 W), and despite prolonged exposure that delivered a total energy of 192 and 266 J, respectively, plaque injury occurred but successful penetration was not achieved. When the power was raised to more than 2 W, plaque penetration occurred with relatively short exposures (5 seconds or more) with a total energy of 12 to 95 J (Fig. 9). Fifteen histologic sections were examined. With one exception findings were similar to those described for the Nd-YAG or carbon dioxide lasers when segments were immersed in saline solution. The difference was that red blood cells and hemoglobin pigment were adherent to and impregnated within the zone of thermal-induced necrosis and coagulation. Small bubbles and vapor were again noted at the tip of the fiber during lasing.

Effects of exposure to Argon laser radiation under saline solution and blood (Table III): Under saline solution, 1 W could not penetrate the plaque after exposure for 60 seconds, but 2 or more W successfully penetrated the plaque with much shorter exposures (Table III). Under blood, 1 W could not penetrate the plaque after exposure for 60 seconds, whereas 2 or more W successfully penetrated with much shorter exposures. Fifteen tissue sections were examined, and findings were similar to these described for the other 2 laser sources. Small bubbles and vapor were noted when lasing under saline solution or blood.

Discussion

This study of the effect of laser radiation on atherosclerotic plaques was undertaken because certain properties of lasers suggested that they could be used to produce controlled tissue damage to blood vessels. These properties of lasers included (1) capacity to photocoagulate tissues, (2) preferential absorption by certain tissues, (3) control of energy output, (4) precise control of beam direction, (5) transmission by way of fiber optics through catheters designed for intravascular use, and (6) possible acceleration of tissue healing.[14–17]

These experiments showed that 3 different types of lasers were capable of damaging atherosclerotic plaques. Laser-radiation damaged plaques composed of either a central lipid core or fibrous proliferation. A moderate degree of calcification did not prevent laser-induced damage. These vessels were obtained at autopsy, and healing and inflammatory responses to laser radiation

were not evaluated. Additional studies will be needed to define chronic tissue responses occurring after laser radiation.

Power and duration of exposure to laser radiation emerged as important variables that could be regulated to produce predictable degrees of arterial injury. As a predictor of the degree of arterial injury, total energy delivered correlated better than either power or duration of exposure alone. Besides total energy, 2 other variables influenced magnitude of arterial injury: first, whether the arterial segment was exposed in air or immersed in saline solution or blood; and second, the type of laser source. Under dry conditions the carbon dioxide laser damaged atherosclerotic plaques with a minimum of 2.5 J of total energy. When the arterial segment was immersed in saline solution, similar damage to the plaque required a total energy >5 J. Compared with results using a saline medium, experiments conducted using the Nd-YAG laser and blood as the media demonstrated that blood-enhanced absorption as less energy was needed to produce plaque damage. Reasons for enhanced tissue absorption were not clear. However, one possibility was that hemoglobin pigments released from lased red blood cells adhered to and became impregnated in the vessel wall increasing laser absorption similar to that seen with Sudan Black. Experiments conducted under blood (Nd-YAG or Argon laser) or saline solution (Argon laser) suggested that a minimal power may exist below which successful plaque penetration did not occur even with prolonged lasing. A minimal amount of power may be necessary under other conditions with these lasers and also with the carbon dioxide laser, but was not apparent at the powers studied.

Several laser sources are available and differences between them may be important. The wavelength of the carbon dioxide is 10,600 nm whereas the wavelength of the Nd-YAG laser is 1,064 nm. The Argon laser has 2 principal wavelengths at 488 and 514 nm. Others have demonstrated that the wavelength of the laser beam is an important determinant of tissue absorption.[8] In these experiments, other than total energy required, no major differences among the 3 lasers were observed regarding plaque damage. Further studies are necessary to explore differences in energy requirements under various conditions among the 3 lasers. Also it seems clinically important that the fiberoptic material necessary to carry the high infrared frequency of the carbon dioxide laser is potentially water soluble and toxic.[18–20] This material is also expensive. Both the Nd-YAG and Argon lasers can be carried by optical fibers that are neither water-soluble nor toxic and they are relatively inexpensive. Both can be delivered through a catheter guided system to appropriate intravascular regions for application.[10,21] Some intermediary agents such as Sudan black but not cardiogreen may enhance surface absorption of the Nd-YAG laser. Enhanced surface absorption may be useful in localizing injury to the plaque and spare surrounding tissue. If this occurs the probability of perforation should decrease. Additional experiments will be needed using various dyes together with saline or blood media to define conditions that enhance superficial absorption and provide an adequate depth of penetration without perforation. Tissue damage produced with other lasers such as Argon and carbon dioxide may also be enhanced by intermediary agents.

In general, the histologic appearance of tissue damage created by the 3 lasers was similar. In each instance 3 zones of damage were noted consisting of an innermost zone of complete tissue vaporization, a second zone of thermal burning, and an outermost third zone of diffuse tissue disruption presumably caused by acoustic or shock injury. All these experiments were done with continuous wave lasers. A pulsed beam-type laser may produce different types of histologic injury.[15]

In conclusion, lasers can be used to damage atherosclerotic plaques. These techniques probably can be adapted to intravascular delivery of the laser beam through guidance systems similar to those used during percutaneous transluminal angioplasty. This experience encourages us to continue to explore further the potential uses of laser radiation to improve perfusion through obstructed arteries.

Transluminal Laser Catheter Angioplasty

DANIEL S. J. CHOY, MD, SIMON STERTZER, MD, HEIDRUN Z. ROTTERDAM, MD, NIGEL SHARROCK, MD, and IVAN P. KAMINOW, PhD

The first transluminal laser angioplasty in animals is reported herein. An Argon laser and a specialized coronary arterial catheter with a fiberoptic wave guide were used. Immediate histologic changes consisted of a moderate degree of intimal necrosis and some loss of elastic tissue. At 5 days the intima was repaired, but focal elastic tissue loss persisted.

In 1978, one of us (DC) conceived of delivering laser energy from an external source through a fiberoptic wave guide to an intraluminal site to vaporize plaque and thrombus obstructions in vessels. Carbon dioxide laser energy was unsuitable because of the high heat generation and the lack of nontoxic wave guides. An Argon laser became the first choice because of its complementary absorption coefficient to hemoglobin and the availability of suitable wave guides. In vitro experiments and in vivo transluminal catheter angioplasty with use of Argon laser energy are described herein.

Methods

Energy source: A Coherent model 800 optical laser was utilized in preliminary in vitro experiments in the laboratories at Lenox Hill Hospital, New York City. This study confirmed the feasibility of vaporizing human thrombi, atherosclerotic plaques, and cartilage with Argon laser energy. Further experiments, using a Coherent model 1000 Argon laser and a delivery system consisting of an 85 μm core, 125 μm cladding silica fiber in a specialized intraarterial catheter, demonstrated that at 4.5 W output, a 1.0 cm tunnel could be bored in a fresh thrombus in 36 seconds. In an artificial vascular system filled with saline solution, an artificial clot subjected to laserization turned to vapor which appeared briefly as thousands of microscopic bubbles that rapidly disappeared in solution.

No analyses have as yet been performed, but because the constituents of a thrombus are mainly carbon and water, we speculate that the largest portion of this vapor is composed of steam and carbon dioxide. This finding is supported by the observation that the gas bubbles had a high degree of solubility in saline solution. We therefore do not anticipate gas embolization to be a problem in vivo. Spectroscopic analyses are underway to determine the exact composition of the vapor.

Another potential problem is heat generation. An exposure of 1.0 second at 3.5 W produces 3.5 J, or 0.84 Cal. With the exception of cartilage and the cores of neoplasms, the tissues of the body are richly invested with a capillary network which, like the cooling system of an internal combustion engine, contributes to thermal homeostasis. Prolonged exposure of tissues to ambient temperature above 44°C leads to irreversible precipitation of DNA and cytoplasmic proteins. The low levels of heat generation in laser angioplasty are unlikely to produce these conditions, especially with active capillary flow acting as a heat sink. We therefore do not believe that heat generation will present an insuperable problem in vivo.

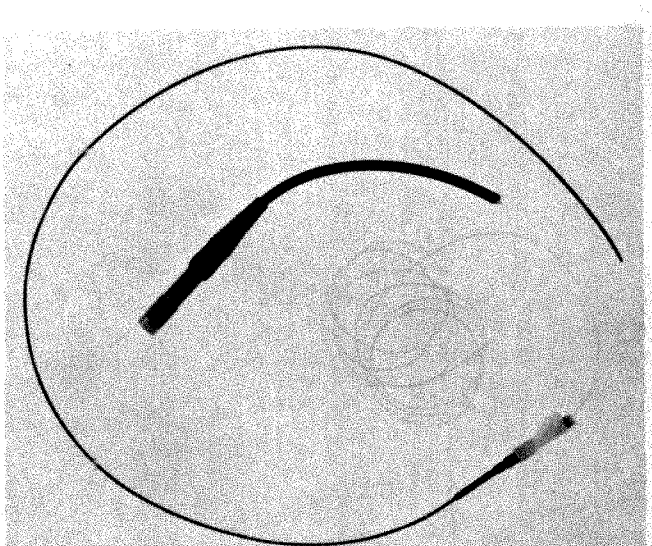

FIGURE 1. Model 4 French laser catheter with optical fiber in lumen. The thick end mates to coherent model 1000 Argon laser.

The artificial thrombi produced here are histologically, but not biochemically, different from organized thrombi in vivo. The laser energy interacts with the physicochemical properties of the thrombi, and is independent of histologic differences. We are therefore cautiously optimistic about extrapolating in vitro results to an in vivo situation.

Delivery system: A laser catheter was invented by one of us (DC) and patented in June 1980 (U.S. Patent 4207874). This device may be briefly described as a fiberoptic wave guide incorporated into a catheter for conducting laser energy from an external source to an intraluminal site for the purpose of tunneling through obstructions of various types. An additional feature is a coherent fiberoptic bundle for endoscopic imaging. This catheter was previously described (by DC) at the International Laser Conference in Shanghai and Beijing in May 1980[1,2] (Fig. 1).

Animal experiments: Laser angioplasty was performed in acute experiments involving (1) the abdominal aorta of a rabbit, and (2) 2 femoral arteries of a dog. In these experiments the rabbit and dog were anesthetized with secobarbital and kept alive during the entire procedure. In the canine experiment, the right femoral artery was used on the first day and the left on the fifth day. An 8.0 cm length of artery was exposed, and a 1.0 cm segment was isolated between 2 ligatures. Human blood, 1.0 ml, and fresh thrombin, 0.2 ml, were injected into the lumen of this segment. After 5 minutes the ligatures were removed, the formation of a complete occlusive thrombus were verified by blanching, loss of distal pulsation, and by pressure tracings in the 4.0 cm of exposed distal artery (Fig. 2). The laser catheter, previously calibrated to deliver 3.0 W at the tip, was introduced proximally and advanced to abut the thrombus. The laser was then switched on.

In the case of the right femoral canine artery, the arteriotomy was repaired with 6-0 Tevdek® sutures and the wound closed. The rabbit was killed on the first day and the dog was killed on the fifth day.

Results

In all 3 instances, the 1.0 cm thrombi were vaporized in ±1.0 second. Patency of the arteries was demonstrated by (1) brilliant blue-green transillumination of the distal arteries which were previously dark; (2) resumption of blood flow and pulsation in the distal arteries; (3) pressure tracings (Fig. 2) in the right canine femoral artery; and (4) histologic sections (Fig. 3 to 5). Pressure tracings on electrocardiographic paper were obtained by inserting a needle transducer into the distal segment of the canine right femoral artery. Each 0.5 cm on the vertical axis represents 40 mm Hg. Baseline systolic pressure was 160 mm Hg. The pressure after angioplasty was 80 mm Hg. Because histologic sections 5 days later revealed complete absence of thrombus, we attribute the 80 mm decrease in pressure to narrowing of the proximal segment caused by repair of the arteriotomy and perhaps to immediate vascular wall edema from laser injury.

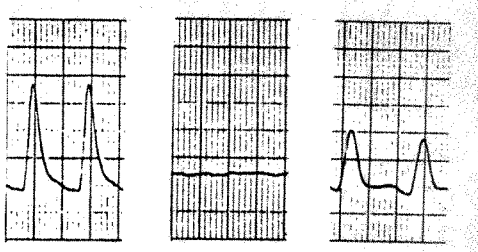

FIGURE 2. Pressure tracings of artery distal to thrombus.

By direct inspection, full flow was reestablished in the arteries distal to the thrombus after laser angioplasty. The blanched, collapsed arteries became full, red, and pulsatile.

In the canine experiment, the 5 postoperative days were uneventful. The animal was afebrile, had an enormous appetite, and was fully ambulatory with clinical evidence of excellent arterial perfusion of the operated leg.

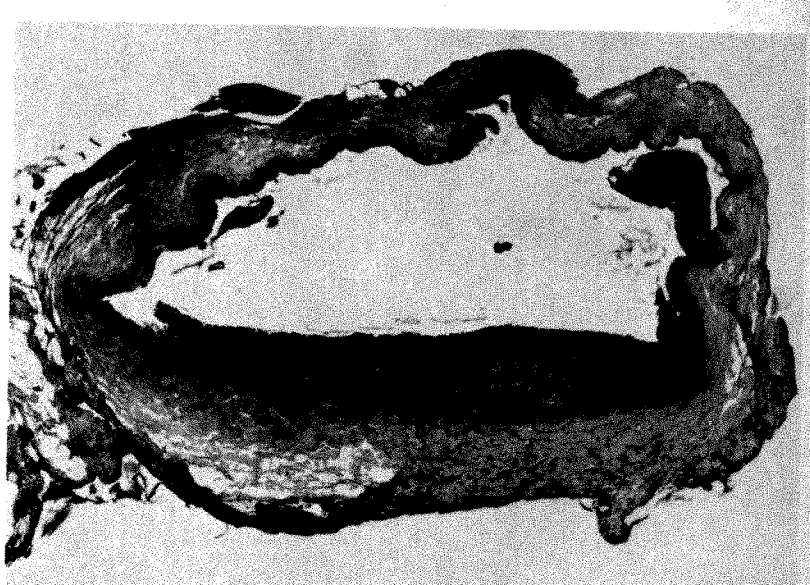

FIGURE 3. Segment of artery at thrombus site after laserization. Note complete absence of thrombus. (Hematoxylin-phloxine saffron stain; magnification X40, reduced 29%.)

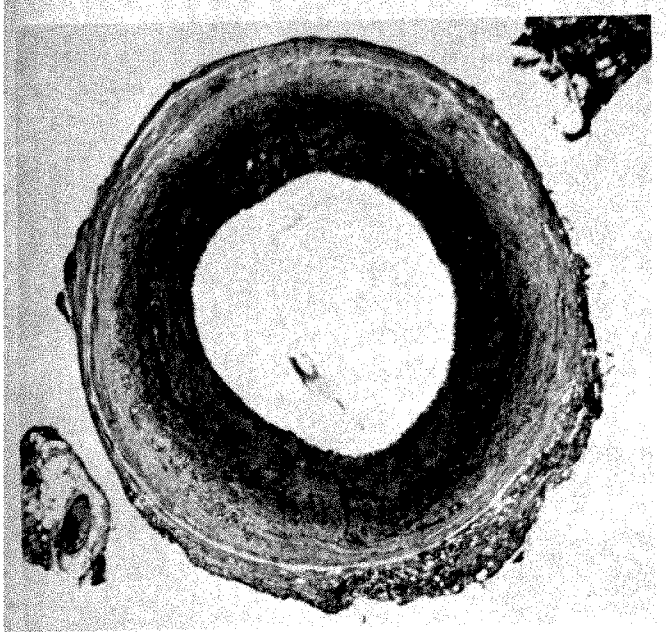

FIGURE 4. Canine femoral artery proximal to thrombus 5 days after laserization. (Hematoxylin-phyloxine saffron stain; magnification ×40, reduced 32%.)

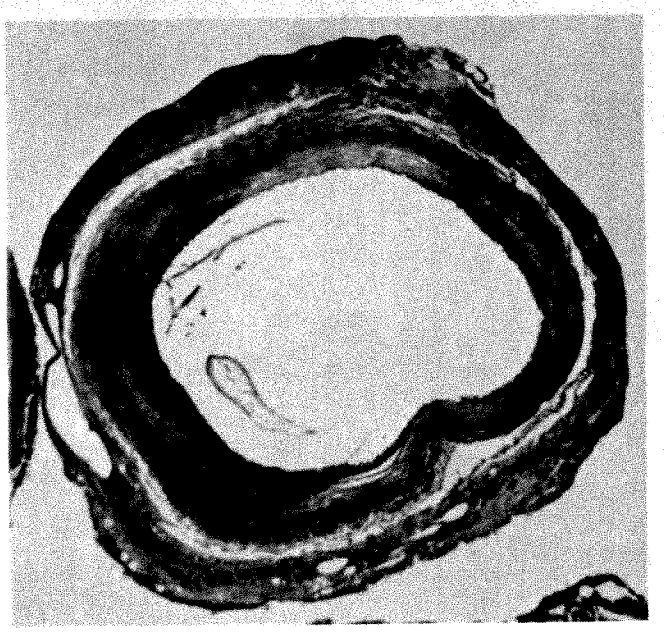

FIGURE 5. Canine femoral artery at the site of thrombus, 5 days after laserization. Note the focal loss of elastic tissue in the media, the absence of thrombus, and the intact endothelium. (Hematoxylin-phloxine saffron stain; magnification ×40, reduced 32%.)

Histology: In the acute experiments, sections of the arteries revealed a moderate degree of intimal necrosis and some loss of elastic tissue in the media in the region of the thrombus (Fig. 3). In the artery examined 5 days after laser angioplasty, the zone of focal medial damage measured 2.2 cm, extending 1.2 cm distal to the thrombus (Fig. 5). However, it is significant that (1) the thrombus was completely vaporized, (2) the intima was completely repaired in 5 days, although some focal elastic tissue loss persisted, and (3) no postlaserization thrombus had formed.

Discussion

Experience with vascular surgery since World War II has demonstrated that damage to the endothelial surface of arteries and veins is followed by deposition of fibrin and platelets, followed by complete endothelial repair in 2 days to 2 weeks, depending on the size of the denuded area.[3] Our finding of complete intimal repair in 5 days is consistent with this experience.

The question of distal embolization of debris arises. Previous in vitro experiments with an artificial vascular tree occluded by thrombus subjected to Argon laser angioplasty revealed total vaporization without debris formation; that is, the clot was turned directly into vapor appearing as thousands of microscopic bubbles that went into solution within 1 second. We believe it is reasonable to extrapolate these results to the in vivo situation. Moreover, there was no clinical evidence of distal embolization.

The discrepancy between the 36 seconds at 4.5 W exposure needed to bore a 1.0 cm tunnel in a free-standing clot and the 1.0 second at 3.0 W exposure needed to vaporize a 1.0 cm long intravascular clot may be explained by the fact that in the former instance the walls of the tunnel, being unsupported, kept collapsing and did not become rigid until carbonization occurred, whereas in the latter case, the vessel provided a supporting scaffold, and vaporization could proceed without continuing collapse of the tunnel walls.

From its inception 4 years ago, the concept of vaporizing intravascular plaques and thrombi by introducing laser energy through a wave guide in a flexible catheter has been shown feasible in in vitro and in vivo experiments.

Laser Coronary Angioplasty: Experience With 9 Cadaver Hearts

DANIEL S. J. CHOY, MD, SIMON H. STERTZER, MD, HEIDRUN Z. ROTTERDAM, MD, and MICHAEL S. BRUNO, MD

Experience with laser angioplasty in 16 coronary arteries in 9 cadaver hearts is presented. Coronary obstructions were due to experimentally created thrombi as well as to naturally occurring calcified plaques. Successful laser angioplasty was achieved in 14 of 15 arteries. One artery was sacrificed to determine factors necessary for deliberate perforation of the arterial wall. This procedure required more than 30 seconds of laser energy at 3.0 W with the catheter tip almost perpendicular to the wall. Penetration of the arterial wall occurred only in the second left anterior descending artery which was plaque-occluded because of operator inexperience.

In a previous report,[1] we described the successful in vivo use of a laser catheter to recanalize arterial thrombotic obstructions in animals. We describe herein further experience using the same system in 16 coronary arteries in 9 cadaver hearts. The study was undertaken as a preliminary investigation leading to the eventual objective of performing percutaneous coronary angioplasty with the laser catheter in vivo, in acute and chronic, total and partial coronary artery occlusive disease.

Methods

Sixteen coronary arteries in 9 cadaver hearts were utilized. All arteries were dissected free from pericardial fat. There were 2 categories:

1. *Diseased arteries* (7): Three of the 7 were completely, and 4 were 70 to 80% (estimated cross-sectional area) obstructed by calcified plaque. This group required no further preparation.

2. *Nondiseased arteries* (9): Artificial thrombi were created in these as follows: A 1.0 cm segment of artery 1.5 to 2.0 cm distal to the ostium was isolated between 2 ligatures of 4-0 silk. A firm thrombus was created in this segment by injecting fresh blood into the lumen together with 0.05 ml of freshly prepared thrombin through a 26 gauge needle. Complete occlusion was then documented by inspection, palpation, and angiography (Fig. 2).

With use of the laser catheter[2,3] invented by one of us (DC) (U.S. patent 4207874) and a Coherent model 1000 Argon laser tuned to a tip output of 1.7 to 4.5 W, the thrombus or plaque was vaporized by introducing the catheter through the coronary artery ostium to the occlusion and switching on the laser in 0.5 to 1.0 second bursts. Between bursts of laser light, the catheter was manually advanced. Completion of tunneling was signalled by brilliant transillumination of the artery distal to the thrombus or plaque site (Fig. 1).

Patency of the artery was documented with repeat angiography (Fig. 2, right).

The arteries were then prepared for histologic examination.

Results (Table I)

Diseased arteries (7): All 3 arteries totally occluded by calcified plaque were successfully canalized with exposures of 3.0 W at 46 seconds, 4.0 W at 42 seconds, and 4.0 W at 38 seconds (experiments 2 and 4).

Two of 2 arteries partially occluded by calcified plaque were canalized with exposures of 1.7 W at 12 seconds (experiment 1, left anterior descending artery [LAD]), and over a 5.0 cm length with 4.5 W at 48 seconds (experiment 8, LAD). In the latter instance, the artery that was previously impenetrable to a 3 French catheter easily admitted an 8 French catheter after laser tunneling.

One subepicardial dye extravasation occurred (experiment 2) when the catheter tip was inadvertently jammed into a shelf between plaque and wall.

In experiment 9, 2 ovoid calcified plaques were vaporized utilizing the following power variables: 8 by 3 by 2 mm plaque, 3.5 W at 3.0 seconds; and 7 by 3 by 2 mm plaque, 3.5 W at 2.5 seconds. Before vaporization, the plaques were seen as dark areas against a transilluminated (Fig. 1) background of normal vessel wall. After vaporization, the plaque areas transilluminated

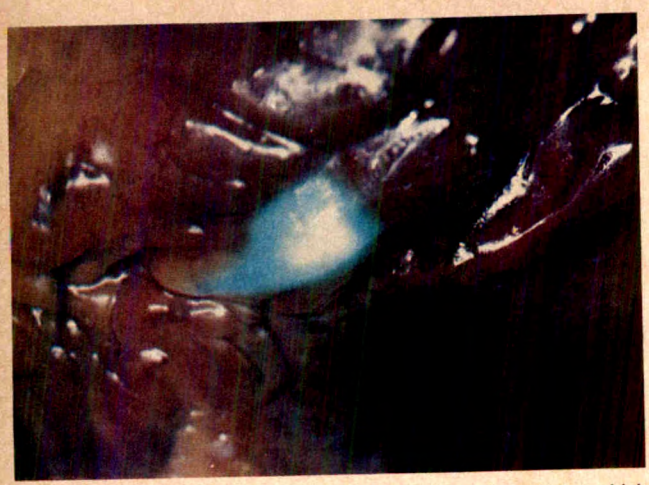

FIGURE 1. Coronary artery transilluminated by Argon laser beam which has vaporized the obstruction.

as well as normal vessel wall. This phenomenon will prove useful in the future use of the laser catheter to vaporize intraluminal plaques during open heart surgery.

Nondiseased arteries (9): The artificially created thrombi were vaporized with no difficulty at exposures ranging from 1.7 W at 4.0 seconds to 4.5 W at 1.0 second. This was accomplished in 8 of 8 arteries.

One artery (experiment 5, right coronary) was used to ascertain exposure time needed to deliberately perforate the wall. With the catheter tip positioned at 80° to the wall, perforation occurred with an exposure of 3.0 W at 30.8 seconds (92.5 J).

Discussion

Successful laser angioplasty was achieved in 8 of 8 coronary arteries that were artificially occluded with fresh thrombi, and in 6 of 7 coronary arteries that were

FIGURE 3. Coronary artery at thrombus site. Note that the thrombus has been completely vaporized with minimal damage to the intima. (Hematoxylin-phloxine-saffron stain. Magnification ×40, reduced 30%.)

naturally occluded, totally and subtotally, with calcified plaque.

The 1 failure in the diseased arteries was due to unfamiliarity with catheter control, causing the catheter tip to be inadvertently insinuated between a shelf plaque and the wall (experiment 2).

In the same experiment, the right coronary artery, completely occluded by calcified plaque, was approached with more careful laser catheter control; that is, the catheter was so manipulated that it was coaxial with the artery during delivery of the laser energy. The plaque was tunneled through by an exposure of 3 W at 46 seconds. Excellent distal runoff was demonstrated with angiography. There was no penetration of the arterial wall.

Why did deliberate perforation of the arterial wall require 30.8 seconds at 3.0 W and inadvertent perforation occur at 3.0 W and 10 seconds? In our opinion, the 20-second differential is due to the fact that in the latter instance the catheter tip was being forcibly pushed against the wall.

Because many thrombotic total and subtotal coronary artery occlusions average 1.0 cm in length, and can be vaporized in 1 second at 4.5 W, it is doubtful that perforation of the arterial wall will be a significant problem in later attempts at in vivo laser coronary artery angioplasty.

This is particularly true because the design of the laser catheter will permit its use only when coaxial with the lumen of the vessel.

In this regard, even total obstructions of calcified plaque (experiment 4) can be vaporized with no danger of perforation through careful manipulation of the catheter.

The histologic section (Fig. 3) demonstrated complete vaporization of thrombus and minimal damage to intima. In previous animal experiments,[1] intimal damage was completely repaired in 5 days, and no postlaserization thrombosis occurred. On that basis, one might expect that with use of antiplatelet and anticoagulant drugs, complete reendothelization would occur within 1 week without postangioplasty thrombosis.

Conclusions: The foregoing data in the pilot animal experiments and in 16 coronary arteries lead us to conclude that (1) damage to intima and accidental perforation of arterial wall by the laser catheter are controllably low incidence risks, and (2) percutaneous laser coronary artery angioplasty under fluoroscopic image intensifier guidance may be a clinical reality in the near future.

Prospective Evaluation of Radionuclide Angiocardiography For the Diagnosis of Coronary Artery Disease

ERLE H. AUSTIN, MD, FREDERICK R. COBB, MD, R. EDWARD COLEMAN, MD, and ROBERT H. JONES, MD

This investigation assesses prospectively the accuracy of rest and exercise radionuclide angiocardiography (RNA) in detecting coronary artery disease (CAD). By retrospective analysis of 496 patients, optimal RNA criteria were determined for the presence or absence of CAD. Multivariate analysis of patients with normal coronary arteries on catheterization provided a formula to predict normal exercise ejection fraction (EF) in a given patient. The presence of CAD was indicated by 1 or more of the following RNA measurements: (1) rest EF <0.50, (2) exercise EF at least 0.06 less than the predicted value, (3) exercise increase in end-systolic volume >20 ml, (4) exercise-induced wall motion abnormality. The absence of CAD was indicated by the absence of all 4 criteria. After applying these criteria to 221 consecutive patients, the RNA determinations were compared with the catheterization determinations. Significant CAD was present in 71% of the patients studied. The sensitivity of the test was 0.87 and the specificity 0.54. Thus, because of its high sensitivity, RNA is of value in screening patients under consideration for cardiac catheterization. No patient with significant left main coronary narrowing and only 4 of 65 patients with 3-vessel disease were misdiagnosed. The poor specificity of the test, however, limits its overall accuracy.

Noninvasive radionuclide techniques for measuring left ventricular function at rest and on exercise have been advocated for diagnosis of CAD.[1–4] These early studies used arbitrary criteria for differentiating an abnormal from a normal study. More recently, the optimal criteria for the detection of CAD by rest and exercise radionuclide angiocardiography in patients being evaluated for chest pain were retrospectively determined and applied to a large patient population.[5] The rest and exercise radionuclide study had a sensitivity of 0.90 and a specificity of 0.58 in 496 retrospectively studied patients. However, it is important to apply criteria optimal for defining a normal and abnormal test in a population other than that used to derive the criteria. Therefore, the purpose of this study was to apply these diagnostic criteria prospectively to a large group of consecutive patients undergoing both rest and exercise radionuclide angiocardiography and coronary angiography.

Methods

Study population: From January 1, 1980 through December 31, 1980, 693 patients underwent initial cardiac catheterization at Duke University Medical Center for the evaluation of CAD. Of this group, 72 patients had a history of valvular or congenital heart disease or previous cardiac surgery. Of the remaining 621 patients, 233 underwent rest and exercise RNA. Twelve patients were excluded because of inability to exercise for at least 5 minutes or achieve an exercise end point of chest pain, electrocardiographic change, or 85% of the maximal predicted heart rate for age. Therefore, the population studied included 221 patients.

Radionuclide angiocardiographic technique: RNA was performed at rest and on exercise exactly as in our earlier retrospective study.[5] A first transit technique was employed using a multicrystal gamma camera (System 77, Baird Corporation) and an intravenous bolus of 15 mCi of technetium-99m pertechnetate. A resting study was performed with the patient sitting erect on a bicycle ergometer (Fitron-Lumex). Exercise was begun at a work load of 200 kpm/min and was increased by 100 kpm/min each minute. End points used to time the exercise study included angina, electrocardiographic evidence of ischemia, 85% of the maximal predicted heart rate, or severe fatigue or dyspnea.

Measurements determined included left ventricular ejection fraction, end-diastolic volume, and end-systolic volume.

The validity and reproducibility of these measurements has been previously established.[6–8] Static and cineangiographic images of left ventricular wall motion allowed qualitative analysis of the anterior, apical, and inferior walls of the left ventricle. Wall motion assessment was derived from the consensus of at least 4 experienced observers without knowledge of the patient's clinical history or coronary angiographic results.

Optimal diagnostic criteria: From a retrospective analysis of 496 patients, optimal criteria for diagnosing the presence of CAD had been derived from measurements of left ventricular function at rest and during exercise.[5] The abnormality of resting ventricular function providing the greatest diagnostic information was an ejection fraction <0.50. Multivariable analysis in 60 patients with chest pain and normal coronary arteries demonstrated that sex, resting ejection fraction, and rest-exercise change in end-diastolic volume were major predictors of the magnitude of normal increase in left ventricular ejection fraction during exercise.[9] The equations used to predict change in ejection fraction with exercise (ΔEF) were as follows: For men, $\Delta EF = 0.45 - 0.5$ (EF at rest) $- 0.002$ (ΔEDVI), and for women, $\Delta EF = 0.385 - 0.5 \times$ (EF at rest) $- 0.002$ (ΔEDVI). An exercise ejection fraction at least 0.06 less than predicted was then determined as 1 of the optimal criteria for the detection of coronary disease. An increase in end-systolic volume >20 ml with exercise and the appearance of an exercise-induced wall motion abnormality were also included as optimal criteria. The relative sensitivity and specificity of each of these criteria were analyzed separately and together in this prospective study.

Statistical analysis: Chi-square analysis was employed to compare the clinical characteristics of the 221 patients in this prospective study with the 621 patients who underwent cardiac catheterization in 1980. A similar comparison was made with the 496 patients from whom the optimal diagnostic criteria were derived.[5]

Results

Clinical characteristics: The clinical characteristics of the prospective group (Table I) were similar to those of all patients with chest pain who underwent initial cardiac catheterization at Duke University Medical Center during 1980. The prospective group was also similar to the 496 patients described in our retrospective study.[5] The incidence of systemic hypertension was significantly higher in patients studied in 1980, but no differences existed in sex or age distribution or frequency of smoking or diabetes. The types and severity of chest pain and extent of CAD also were similar.

Correlation of RNA results with presence of CAD (Table II): The resting RNA ejection fractions of patients with and without significant CAD are depicted in Figure 1. Only 1 patient without CAD had a resting ejection fraction <0.50 (specificity 0.98). The sensitivity for this criterion alone, however, was only 0.23 (Table II).

TABLE II Prevalence of Positive Tests in Patients With and Without CAD

EF = left ventricular ejection fraction; ESV = left ventricular end-systolic volume; Ex = exercise; LM = left main coronary artery disease; V = vessel.

The differences from predicted exercise ejection fraction for patients with resting ejection fractions >0.50 are illustrated in Figure 2. Differences in patients with CAD tended to fall further from predictions, but significant overlap existed between the 2 groups. Using the criterion of 0.06 or more below predictions to indicate disease, the specificity of exercise ejection fraction alone was 0.63 and the sensitivity was 0.73 (Table II).

The changes in end-systolic volume with exercise in the patients with resting ejection fraction >0.50 are depicted in Figure 3. Again, much overlap was observed between patients with and without disease. A cutoff of a 20 ml increase provided a specificity of 0.90 and a sensitivity of 0.50 for this criterion alone (Table II).

Of the 183 patients with a resting ejection fraction >0.50, an exercise-induced wall motion abnormality was present in 61% of patients with disease (sensitivity) and absent in 79% of patients without disease (specificity). If all 3 exercise criteria were required to define CAD presence, the specificity increased to 0.94 and the sensitivity decreased to 0.37. Requiring any 1 of the 3 exercise criteria decreased the specificity to 0.55 and increased the sensitivity to 0.83 (Table II).

The greatest sensitivity was observed for the entire group when any 1 of the 4 criteria (resting EF <0.50, difference in exercise EF of at least 0.06 less than predicted, increase in end-diastolic volume >20 ml, or exercise-induced wall motion abnormality) was present. Of the patients with CAD, 87% were identified correctly using these criteria. Moreover, no patient with significant left main coronary narrowing and only 4 of 65 patients with 3-vessel disease were incorrectly diagnosed. The specificity of the test using all 4 criteria, however, was 0.54 as only 34 of the 63 patients without significant disease had a negative result.

False-positive findings: By requiring only 1 of 4 criteria to determine the presence of CAD, 29 (46%) of the 63 patients without CAD were misdiagnosed. Seventeen (55%) of 31 women and 12 (38%) of 32 men without CAD were designated as having CAD by 1 or more of the 4 criteria. Twelve of the 29 false-positive findings were positive only by an exercise ejection fraction of 0.06 or more below predicted. Two false-positive results occurred solely because of an exercise increase in end-systolic volume >20 ml. Three other false positives resulted from isolated exercise-induced wall motion abnormalities. One false positive occurred from a low resting EF. One patient with a false-positive finding had a positive exercise ejection fraction and exercise end-systolic volume. Seven false-positive findings were associated with both exercise-induced wall motion abnormalities and exercise ejection fractions 0.06 or less than predicted. Three false-positive results were positive for all 3 exercise criteria. The age distribution of the patients with false-positive findings (range 27 to 62 years, mean 49.8) was representative of the entire group studied (range 27 to 70 years, mean 51.6). The frequency of systemic hypertension, diabetes mellitus, and smoking in the patients with false-positive results was similar to that in all 221 patients. Typical chest pain was less common (5 of 29) and nonanginal (5 of 29) and atypical (19 of 29) chest pain were more common among the patients with false-positive findings

TABLE III Overall Accuracy of Rest and Exercise Radionuclide Angiocardiography in the Diagnosis of Coronary Artery Disease: A Prospective Study

	165 Men	56 Women	221 Patients
Disease prevalence	0.82	0.45	0.71
Sensitivity	0.87	0.84	0.87
Specificity	0.63	0.45	0.54
Predictive value			
Positive test	0.91	0.55	0.83
Negative test	0.51	0.78	0.60
Efficiency	0.82	0.63	0.77

than in the entire group. Of the 29 patients with false-positive findings, 22 achieved 85% of the maximal predicted heart rate for the exercise study (compared with 105 of 221). The mean heart rate and systolic blood pressure achieved during exercise in the patients with false-positive findings were 153 beats/min and 164 mm Hg, compared with 144 beats/min and 156 mm Hg for the whole group. Six of 29 had chest pain (63 of 221), and 3 of 29 (69 of 221) exhibited electrocardiographic changes during exercise. The mean exercise work load was 690 kpm/min for the patients with false-positive findings and 710 kpm/min for the entire group.

Differences between men and women: RNA diagnosis of CAD was more accurate in men than in women (Table III). The sensitivity of the test using the 4 criteria was similar in both men and women (0.87 and 0.84, respectively), but the specificity in women was 0.45 compared with 0.63 in the men. The disease prevalence was lower in the women (0.45 for women versus 0.82 for men). A positive test was highly predictive of the presence of disease in men (0.91) but less predictive in women (0.55). A negative test had a higher predictive value in women (0.78) than in men (0.54). Of the men, 82% were correctly classified by the test, whereas only 63% of the women were correctly identified.

Influence of other factors on diagnostic accuracy: Twenty-one patients (9.5%) were taking propranolol at the time of study. Only 2 patients receiving this medication were misdiagnosed (2 false-positive results). Four patients were found to have a prolapsing mitral valve; none of these 4 had significant CAD. Two of these patients were correctly diagnosed as having no CAD and the other 2 had false-positive exercise ejection fractions.

Discussion

Early studies using RNA at rest and on exercise demonstrated that in normal subjects ejection fraction increased with exercise, whereas in patients with ischemia from CAD, ejection fraction decreased with exercise.[1,10] Further studies have shown that increases in left ventricular end-systolic volume[11,12] and the development of wall motion abnormalities[2–4] with exercise can also be sensitive and specific indicators of significant CAD. These studies, however, involved small groups of patients, often including asymptomatic volunteers. From our earlier experience with 496 patients undergoing cardiac catheterization for chest pain, we combined resting ejection fraction and exercise-induced changes in ejection fraction, end-systolic volume, and wall motion to determine optimal RNA criteria for diagnosis of CAD.[5] The sensitivity and specificity determined in this prospective study were similar to those derived in that retrospective analysis.

An overall test sensitivity of 0.87 compares favorably with other noninvasive techniques for detecting CAD. Electrocardiographic treadmill testing in large groups of patients presenting with chest pain has been shown to have a sensitivity of 0.70 to 0.80.[13–15] In 187 patients at our institution undergoing both treadmill testing and rest and exercise RNA, the sensitivity of RNA was 0.86 compared with 0.73 for treadmill testing.[5] Thallium myocardial perfusion imaging has been shown to have a sensitivity of 0.56 to 0.93.[14–19] Thallium imaging was not employed in the present study, and a direct comparison cannot be made. Nevertheless, rest and exercise RNA appears to offer a sensitivity for the detection of CAD that surpasses that of treadmill testing and at least equals that of thallium imaging.

The major limitation of rest and exercise RNA is the low specificity of 0.54. Early reports of specificity for RNA[2–4] were much higher than our present findings but were not determined from a large group of consecutively studied patients. Caldwell et al,[18] in an analysis of 52 patients, described a similar level of specificity (0.54) for RNA. The specificity for thallium imaging in the same patients with 1.0. Although few other reports of thallium imaging attest to perfect specificity, specificity of thallium imaging commonly exceeds 0.85.[14–19] The specificity of electrocardiographic treadmill testing ranges between 0.64 and 1.0.[13–17] In our own analysis of 187 patients with both electrocardiographic treadmill testing and radionuclide angiocardiography, the specificity of treadmill testing was 0.80 compared with 0.61 for RNA.[5] Thus, the specificity of rest and exercise RNA is less than attainable by treadmill testing or thallium imaging.

The poor specificity of the test may be due in part to the reliance upon measurements of global function. Conditions other than CAD may display global abnormalities, whereas CAD has been expected to exhibit more regional dysfunction.[20] The use of wall motion analysis alone, however, in this study failed to identify 40% of patients with significant CAD. Thus, until newer techniques for objectively measuring segmental wall motion are shown to be sensitive as well as specific, measurements of global function will be necessary. The specificity of the test may improve with better understanding of the normal ventricular response to exercise. In 229 patients chosen for defining RNA exercise criteria, inclusion of sex, resting ejection fraction, and change in end-diastolic volume with exercise to predict exercise ejection fraction improved the test specificity from 0.60 to 0.76 without altering the sensitivity.[5] A diminishing ejection fraction response to exercise with increasing age also was recently described.[21] Age, however, was not a major factor affecting specificity in the present study.

RNA test specificity was especially poor in women, as more than half of the women without CAD had positive test results. The incidence of positive tests in patients without CAD was higher for women in both the prospective and retrospective studies. In neither study was the incidence of false-positive tests in women significantly higher than that in men. If both studies are combined, the 56% (44 of 79) incidence of positive tests in women without CAD was significantly higher ($p = 0.044$ by chi-square analysis) than the 40% (35 of 87) incidence in men without CAD. The strength of this observation will depend on the results in a larger number of patients, but a fundamental difference in left ventricular response to exercise may exist between men and women. Similar problems with test specificity in women have been observed with electrocardiographic treadmill testing.[22] Why women should respond differently to exercise than men is not known, but the high incidence of "abnormal" studies in women without CAD may reflect the presence of a cardiac abnormality not detected by coronary angiography, such as exercise-induced coronary spasm. Whatever unknown factors may be involved, rest and exercise RNA is of limited value as a diagnostic test in women.

Thus, because of its low specificity, rest and exercise RNA is not recommended as a screening test for an asymptomatic population or as a diagnostic test for women with chest pain. However, because of its high sensitivity, especially for severe CAD, it is recommended for men with chest pain who are being considered for cardiac catheterization. If a positive RNA had been a requirement for catheterization in the 165 men in the present study, 37 patients (22%) would not have undergone catheterization. Seventeen patients with significant CAD would not have been detected, but 13 of them had only 1- or 2-vessel disease. No patient with significant left main narrowing and only 4 of the 57 patients with 3-vessel disease would have been missed. Because an occasional patient with 3-vessel disease will have a normal rest and exercise RNA, we do not at this time advocate requiring a positive RNA before proceeding to angiography. Nevertheless, in our experience no patient with any extent of CAD who has had normal rest and exercise findings on RNA has died during follow-up from 6 to 60 months. Preliminary information suggests that patients with left ventricular dysfunction during exercise may be more at risk for myocardial infarction or death than are patients with a normal response, irrespective of the number of vessels diseased. Therefore, the more important clinical use of measurements of ventricular function during rest and exercise may be the selection of patients who would benefit most from myocardial revascularization.

Serial Right Ventricular Thallium-201 Imaging After Exercise: Relation to Anatomy of the Right Coronary Artery

KENNETH A. BROWN, MD, CHARLES A. BOUCHER, MD, ROBERT D. OKADA, MD, H. WILLIAM STRAUSS, MD, KENNETH A. McKUSICK, MD, and GERALD M. POHOST, MD

The relation of the appearance of the right ventricle on serium thallium-201 myocardial imaging to coronary artery anatomy was examined in 88 consecutive patients undergoing exercise thallium-201 testing and coronary angiography for the evaluation of chest pain. Transient defects in the right ventricle were found in 8 patients. All had high grade (≥90%) stenosis of the proximal right coronary artery. Nonvisualization of right ventricular (RV) activity occurred in 10 patients. Nine of the 10 (90%) had significant (≥50% stenosis) disease of the proximal right coronary artery and 7 (70%) had high grade stenosis. The right ventricle appeared normal in 70 patients. Twenty-nine (41%) of these patients had significant proximal right coronary artery disease. Right ventricular appearance was not affected by the presence or absence of disease of the left anterior descending or left circumflex artery or by the appearance of the left ventricle.

Thus, with serial RV thallium-201 myocardial imaging after exercise, we found that (1) RV transient defects suggest the presence of high grade proximal right coronary artery stenosis, (2) nonvisualization of RV activity also predicts significant proximal right coronary disease, and (3) the right ventricle frequently appears normal despite proximal right coronary artery disease and therefore this finding does not exclude such disease.

Several recent reports[1–3] have described an abnormal RV ejection fraction response to exercise in the presence of proximal right coronary artery disease. This response may result from inadequate RV perfusion during exercise with resulting RV ischemia. Serial thallium-201 imaging is useful in the evaluation and perfusion and detection of ischemia. However, the relation between RV perfusion, as assessed by thallium-201 imaging, and right coronary artery anatomy has not been analyzed in detail. Although isolated cases of abnormal RV thallium-201 activity associated with proximal right coronary artery disease have been reported,[4] previous studies of myocardial perfusion using thallium-201 have concentrated on left ventricular activity.

In the present study we assessed the relation of serial RV thallium-201 distribution and redistribution to right coronary artery anatomy in 88 consecutive patients after upright exercise. In addition, because the left ventricular wall is generally supplied by the right coronary artery, thallium-201 distribution in the left ventricular inferior wall was also examined.

Methods

Patient population: Serial thallium-201 imaging was performed in 88 consecutive patients admitted for coronary and left ventricular cineangiography for the evaluation of chest pain. Radionuclide imaging and catheterization procedures were performed within 2 weeks of each other. Neither propranolol nor nitrate administration was discontinued for the study. No patient had clinical, electrocardiographic, or radiologic evidence of right ventricular hypertrophy, lung disease, congestive heart failure, or valvular heart disease.

Exercise protocol: An intravenous cannula was inserted just before the exercise test and a baseline 12-lead electrocardiogram was recorded with each patient in the supine and standing positions and during hyperventilation. Patients were then exercised on a treadmill according to the Bruce protocol[5] until fatigue or significant chest pain developed. Heart rate, blood pressure, and a 12-lead electrocardiogram were recorded every minute, and a V_5 lead was continuously monitored. A dose of 1.5 mCi of thallium-201 (New England Nuclear, North Billerica, Massachusetts) was injected intravenously at peak exercise and the patient was encouraged to continue exercising

for an additional 45 seconds. A positive ischemic electrocardiographic response was defined as S-T segment depression ≥1 mm both at the origin and 80 ms later.

Image acquisition: Imaging was performed with the patient supine using an Anger-type camera (Ohio Nuclear Series 420, Technicare, Solon, Ohio) equipped with a low energy all-purpose parallel hole collimator. Images were recorded using a window of 68 to 80 keV encompassing the mercury x-ray peak of thallium-201. Imaging was begun within 5 minutes of cessation of exercise. Image collections were performed in the anterior, 45° left anterior oblique, and 70° left anterior oblique views for 10 minutes each. Delayed views were obtained in 2 to 4 hours. Images were stored in a commercially available imaging computer system for analysis (MUGA-CART, Medical Data Systems, Ann Arbor, Michigan).

Imaging analysis: RV thallium-201 activity was analyzed in the left anterior oblique view which best separated the right from the left ventricle (Fig. 1). The RV appearance was graded by at least 2 independent observers in a blind manner without knowledge of the coronary angiographic results as follows: 0 (absent), 1 (reduced activity compared with that of the left ventricle, but clearly defined), or 2 (prominent, equal to the left ventricle in intensity). Half-grade scores were used to describe right ventricles that were either present but very faint and poorly defined (such as 0.5) or prominent but not quite equal to the left ventricle in intensity (such as 1.5). Differences in interpretation were resolved by consensus. Studies were shown on 2 occasions to allow determination of intraobserver agreement. When the right ventricle was initially graded 1.0 (clearly defined) or more, RV activity was termed "normal" (Fig. 2). When RV activity was initially graded 0 or 0.5 (not visualized or poorly defined) and increased to grade 1.0 (clearly defined) or better on the delayed view, the right ventricle was interpreted as demonstrating a "transient defect" (Fig. 2). When the right ventricle was graded 0 or 0.5 on both initial and delayed views, RV activity was interpreted as "nonvisualized" (Fig. 2). No right ventricle demonstrated initial activity of grade 1.0 that increased on the delayed view.

Interobserver agreement on RV interpretation was 92% for normal, 88% for transient defect, and 90% for nonvisualization. Intraobserver agreement on RV interpretation was 94% for normal, 88% for transient defect, and 90% for nonvisualization.

The serial left ventricular inferior wall thallium-201 distribution was analyzed in the anterior view and categorized as normal, transient defect, or persistent defect using averaged score criteria as previously described.[6] In addition, thallium-201 lung activity was qualitatively graded as 0 (normal), 1 (moderately increased), or 2 (markedly increased) using previously described criteria.[7]

Coronary angiographic data: All patients underwent selective coronary cineangiography. Coronary arteries were defined as demonstrating significant disease when luminal diameter was reduced ≥50% in 2 or more projections. Coronary dominance was noted: the posterior descending artery originated from the right coronary artery in 80 patients and from the left circumflex artery in 8. Proximal stenosis of the right coronary artery was defined as proximal to the origin of the acute marginal artery.

Patients were categorized by their coronary anatomy on the basis of the adequacy of blood supply to the right ventricle and left ventricular inferior wall. The 4 categories were based on the presence of stenosis in the right coronary or posterior descending artery system, or both, which indicated jeopardy of (1) the right ventricle and inferior wall, (2) the right ventricle alone, (3) the inferior wall alone, and (4) neither the right ventricle nor the inferior wall. The rationale for this division was derived from previous observations that the right ventricle is supplied primarily by the acute marginal branch of the right coronary artery and muscular branches proximal to this vessel, whereas the left ventricular inferior wall is supplied primarily by the posterior descending artery.[8–10] Thus, the coronary anatomy in the 4 groups was as follows (Table I): (1) proximal right coronary artery disease associated with significant stenosis proximal to the origin of the posterior descending artery (whether it originated from the right or left circumflex artery), (2) proximal right coronary artery disease without significant

2	+	−	+	−*
3	−	+	−	+†
4	−	−	−	−

* Patients with a normal dominant left circumflex artery.
† Patients with distal right coronary disease or with normal right coronary and disease of a dominant left circumflex artery.
PDA = posterior descending artery; RCA = right coronary artery.

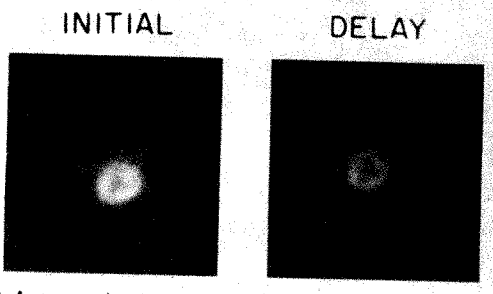

FIGURE 3. An example of nonvisualization of the lower half of the right ventricle in a patient with proximal right coronary artery disease.

stenosis proximal to the origin of the posterior descending artery (normal dominant left circumflex artery), (3) significant stenosis proximal to the origin of the posterior descending artery without proximal right coronary disease (distal disease of a dominant right coronary artery or disease of a dominant left circumflex artery with a normal nondominant right coronary artery), (4) neither proximal right coronary disease nor significant stenosis proximal to the origin of the posterior descending artery.

Collateral vessels to the right coronary artery from the left coronary artery were defined as good when on left coronary injection there was dense contralateral filling of the right coronary artery distal to a stenosis and defined as poor when there was no or only faint contralateral filling. Stenosis <90% of the right coronary artery was always associated with poor collateral vessels in both groups. Therefore, the relation of RV thallium distribution to collateral vessels was only evaluated in patients with right coronary artery stenosis ≥90%.

Statistical analysis: Frequency comparisons between patients were made using Fisher's test or the chi-square test. Mean data were expressed as mean ± 1 standard deviation and differences analyzed using one-way analysis of variance followed by a Neuman-Keuls multiple comparison test.

Results

RV appearance on thallium-201 myocardial images: Representative initial thallium-201 images displaying RV distribution in a patient without angiographic coronary artery disease are shown in Figure 1. The RV activity was generally best seen on the 45° left anterior oblique view. It appeared as a homogeneous semicircular ring from the apical to the basal portion of the septum. Frequently, the upper right ventricle adjacent to the basal septum was absent (Fig. 1), which probably corresponded to the point at which the RV free wall thins as it joins the pulmonary outflow tract. However, this area did not account for greater than a 10° portion of the entire right ventricle in normal subjects. The right ventricle usually appeared thinner and less bright than the septum, although in 2 patients without coronary disease the RV intensity was equal to that of the septum. In some patients, the right ventricle was best seen in the 70° left anterior oblique view, when it generally appeared curvilinear, extending from the apex toward the base. RV activity was not usually seen on the anterior view because of the superimposition of the left ventricle. The majority (80%) of patients, including all 15 patients without coronary artery disease, demonstrated normal right ventricular uptake of thallium-201.

Transient defects of the right ventricle were observed in 8 patients (9%) after exercise (Fig. 2). All RV transient defects involved both upper and lower halves, that is, the entire right ventricle. Nonvisualization of the right ventricle was observed in 10 patients (11%) after exercise. Two patients demonstrated nonvisualization isolated to the lower half of the right ventricle (Fig. 3). The remaining 8 patients had persistent nonvisualization of the entire right ventricle (Fig. 2).

Clinical findings: Table II shows clinical findings in relation to serial RV thallium-201 distribution after exercise. Of 88 patients, 17 (19%) had previous inferior myocardial infarction, but no patient had clinical evidence of a previous RV infarction.

There was no significant difference in age, sex, use of propranolol, incidence of previous inferior myocardial infarction, or incidence of exercise-induced inferior S-T segment depression in patients with normal right ventricular thallium activity, transient defects, or nonvisualization. The maximal exercise systolic blood

LV = left ventricular; PDA = posterior descending artery; RCA = right coronary artery.

pressure, maximal heart rate, maximal blood pressure-heart rate product, duration of exercise, and incidence of achieving 85% of the maximal predicted heart rate were all significantly lower in patients with right ventricular transient defects than in those with normal right ventricular images. In contrast, only maximal systolic blood pressure and maximal heart rate were significantly lower in patients with nonvisualized RV activity than in patients with normal RV thallium-201 distribution.

Coronary angiographic findings: The relation of RV thallium-201 distribution after exercise to coronary angiographic findings is demonstrated in Table III. Significant proximal right coronary artery disease was present in 8 of 8 (100%) patients with RV transient defects and 9 of 10 (90%) patients with nonvisualization of the right ventricle (including both patients with nonvisualization of only the lower half), compared with 29 of 70 (41%) patients with a normal RV appearance ($p < 0.005$ versus transient defect and nonvisualization). All 8 patients with RV transient defects had high grade (≥90%) stenosis of the proximal right coronary artery compared with that in 7 of 10 patients with nonvisualization (p = not significant) and 18 of 70 (26%) patients with normal RV distribution ($p < 0.001$).

Table III also shows the relation of left ventricular inferior wall thallium-201 distribution to coronary angiographic findings. Significant stenosis proximal to the origin of the posterior descending artery was present in 11 (85%) of 13 patients with transient defects of the inferior wall and 25 (86%) of 29 patients with persistent defects of the inferior wall compared with 16 (35%) of 46 patients with normal inferior wall appearance ($p < 0.001$) versus transient and persistent defects).

In 43 patients with both proximal right coronary disease and disease proximal to the origin of the posterior descending artery, the incidence of RV abnormality (15, or 35%) was significantly lower than that of inferior wall defects (30, or 70%) ($p < 0.001$). Of 3 patients with proximal right coronary disease without disease proximal to the origin of the posterior descending artery, 2 had RV abnormalities whereas 1 had an inferior wall defect. Of 9 patients with disease proximal to the origin of the posterior descending artery without proximal right coronary disease, all had a normal RV appearance whereas 6 had inferior defects. When there was neither proximal right coronary disease nor disease proximal to the origin of the posterior descending artery, the incidence of abnormal RV appearance (1 of 33, 3%) was not significantly different from that of inferior wall defects (5 of 33, 15%).

The incidence of left anterior descending artery disease was not significantly different in patients with normal RV appearance (60%), transient defects (75%), or nonvisualization (70%). In addition, left circumflex artery disease did not differ among the 3 groups. Similarly, the frequency of left ventricular thallium-201 defects other than inferior wall defects did not differ among the 3 patient groups.

The relation of collateral vessels to right ventricular thallium distribution is demonstrated in Table IV. Among patients with ≥90% stenosis of the proximal right coronary artery, normal RV appearance was more likely to occur when collateral vessels to the right coronary artery were graded as good (13 of 18, or 72%) than when they were graded as poor (5 of 15, or 33%) ($p < 0.05$).

The relation of degree of exercise (as assessed by heart rate response) to proximal right coronary disease and RV appearance is shown in Table V. RV thallium abnormalities in patients with proximal right coronary disease were more common when the heart rate response was less than 85% of maximal predicted values than when such a level of exercise was achieved ($p < 0.01$).

Relation to thallium-201 lung activity: The relation of RV thallium-201 uptake to thallium-201 lung

TABLE IV RV Thallium Distribution and Collateral Vessels Associated With ≥90% Stenosis of the Right Coronary Artery

Collateral Vessels	RV Thallium-201 Distribution					
	Transient Defect		Nonvisualization		Normal	
	n	%	n	%	n	%
Good	3	17	2	11	13	72
Poor	5	33	5	33	5	33

TABLE V Relation of Heart Rate Response to Exercise and Proximal Right Coronary Artery Disease to RV Thallium-201 Appearance

Proximal RCA Disease	≥85% Maximal Predicted Heart Rate	RV Thallium-201 Distribution: Transient Defect (n = 8)	Nonvisualization (n = 10)	Normal (n = 70)
Yes	Yes	0	3	12
Yes	No	8	6	17
No	Yes	0	0	19
No	No	0	1	22

RCA = right coronary artery.

TABLE VI Relation of RV Thallium-201 Distribution to Thallium-201 Lung Activity

Thallium-201 Lung Activity	RV Thallium-201 Distribution: Transient Defect (n = 8)	Nonvisualization (n = 10)	Normal (n = 70)
0 (normal)	4	3	25
1 (moderately increased)	3	7	27
2 (markedly increased)	1	0	17

activity is shown in Table VI. There was no significant difference in the distribution of RV thallium-201 patterns among the 3 groups of lung activity scores. However, despite proximal right coronary disease (false normal), normal right ventricular appearance was more likely to occur when lung activity was markedly increased (11 of 17) than when lung activity was normal (5 of 25) ($p < 0.01$).

Discussion

The association of left ventricular thallium myocardial defects with disease of coronary blood supply to the left ventricle is well accepted. However, few studies evaluate the diagnostic significance of the appearance of the right ventricle on thallium-201 myocardial imaging. Because of its lesser mass and blood supply[11,12] compared with those of the left ventricle, RV activity is usually not seen on resting thallium-201 studies.[13] Several reports have demonstrated that visualization of the right ventricle on resting studies may occur with right ventricular volume or pressure overload.[14,16] The right ventricle is usually well visualized in normal patients after exercise.[13] Significant stenosis of the coronary supply of the right ventricle might be expected to result in reduced perfusion of the right ventricle, reflected in reduced initial uptake in thallium. In this study, we found that such perfusion imaging abnormalities were relatively uncommon in the setting of proximal right coronary artery disease and were less frequent than left ventricular inferior wall defects (sensitivity 17 of 46, or 37 %, versus 31 of 46, or 67%, respectively). However, when they occurred, they were highly specific for proximal right coronary disease and in the case of right ventricular transient defects were always associated with high grade (≥90%) stenosis.

We have distinguished between transient RV defects and persistent nonvisualization of the right ventricle on serial myocardial imaging. Previous reports showed that with serial thallium-201 imaging, transient left ventricular defects suggest underperfused but viable myocardium, whereas persistent left ventricular defects suggest underperfused and scarred myocardium.[17,18] In the present study we were unable to determine whether the difference between transient and persistent defects applies to the right ventricle. Although segmental nonvisualization of the right ventricle limited to the lower half of the free wall was observed in 2 patients with proximal right coronary artery disease, no patient in the present series was known to have a RV myocardial infarction by clinical criteria and no pathologic (postmortem) data were available. In addition, although RV infarction has commonly been associated with left ventricular inferior myocardial infarction,[19,20] in our study the incidence of previous inferior infarction was not significantly different in patients with transient defects and those with persistently nonvisualized RV activity. Furthermore, radionuclide angiography, which might have assisted in detecting RV infarction, was not performed.

Potential diagnostic limitations of RV appearance: Poor visualization of the right ventricle on thallium-201 imaging may be caused by factors other than proximal right coronary disease. One factor may be inadequate exercise. RV activity is normally not discernible in studies at rest, and in a patient whose exercise is suboptimal, RV blood flow and thallium uptake may not increase adequately to allow visualization of the right ventricle. Such a study could result in interpretation of the right ventricle as "nonvisualized" even in the presence of a normal right coronary artery. In our study, heart rate response and blood pressure response to exercise was lower in patients with a nonvisualized compared with a normal RV appearance. In addition, abnormalities of RV appearance were more common among patients with submaximal heart rate response to exercise. However, such abnormalities occurred almost exclusively in patients with proximal right coronary artery disease. Of 23 patients without proximal right coronary disease who did not achieve adequate heart rate response, only 1 (4%) had nonvisualization of the right ventricle and none had a transient defect (Table IV). A second factor could include increased thallium-201 lung activity, which may result in nonvisualization of the right ventricle by reducing the myocardial-background ratio. In our study, however, increased lung activity was not associated with an increased incidence of nonvisualized segments or transient defects.

Conversely, there are also several factors that may result in normal RV appearance despite significant proximal right coronary disease. One factor would include any cause of increased RV work load or hypertrophy, such as chronic lung disease or pulmonary hy-

pertension of any cause, which is known to increase RV blood supply and thallium-201 uptake. A similar phenomenon may occur with transient increases in pulmonary vascular pressure secondary to exercise-induced left ventricular dysfunction, which is associated with increased thallium lung activity.[27] This possibility is suggested by our observation that there was a higher incidence of normal RV appearance in the presence of proximal right coronary disease in patients with markedly increased thallium-201 lung activity after exercise than in patients with normal lung activity. In addition, exercise may increase RV work and blood supply, and thus thallium-201 uptake to allow visualization of the right ventricle even in the presence of right coronary artery stenosis. This finding may explain why abnormalities of RV appearance in patients with proximal right coronary disease were less common among those who achieved 85% maximal predicted heart rate than in patients who failed to reach such a level of exercise (Table IV). Another factor influencing RV appearance in patients with proximal right coronary disease may be the status of collateral vessels. In our study, normal RV appearance with high grade proximal stenosis was more common when collateral vessels were good than when they were poor. Lastly, because RV uptake was generally less than left ventricular activity, even in normal patients, an abnormality was judged present only when the right ventricle was not clearly visualized on an initial image. Thus, proximal right coronary stenosis could cause reduced but still discernible RV uptake that is not qualitatively distinguishable from RV activity in normal patients. This is unlike left ventricular segmental scoring in which 1 wall is graded in relation to another and may account for the greater sensitivity of left ventricular inferior wall defects for proximal right coronary disease than RV abnormalities. Future quantitative analysis of RV activity may improve sensitivity for right coronary artery disease.

Diagnostic value of serial RV thallium-201 imaging: Despite potential limitations as outlined, our study showed that evaluation of RV appearance on serial thallium-201 myocardial imaging after exercise may provide useful information with respect to proximal right coronary artery disease: (1) transient defects of the right ventricle after exercise suggest high grade (≥90%) proximal stenosis of the right coronary artery; (2) nonvisualized RV activity after exercise also suggests the presence of significant (≥50%) proximal right coronary artery disease; (3) normal RV appearance, however, frequently occurs despite significant proximal right coronary artery disease and thus does not exclude such disease.

Enhanced Transcardiac l-Norepinephrine Response During Cold Pressor Test in Obstructive Coronary Artery Disease

HILTRUD S. MUELLER, MD, PARINAM S. RAO, PhD, PULIPAKA B. RAO, MD, DENNIS J. GORY, MD, J. GERARD MUDD, MD, and STEPHEN M. AYRES, MD

An increase in cardiac sympathetic activity can enhance coronary vasomotor tone and lower the ventricular fibrillation threshold. We compared the transcardiac l-norepinephrine responses during cold pressor test of 20 patients with normal coronary arteries with those of 23 patients with obstructive coronary artery disease. Baseline hemodynamic data did not differ in the 2 patient groups except for left ventricular end-diastolic pressures; mean values (± standard deviation [SD]) were 10 ± 3.7 and 15 ± 4.5 mm Hg in patients with normal and abnormal coronary arteries ($p < 0.01$). Baseline l-norepinephrine contents averaged 295 ± 152 (normal coronary arteries) and 250 ± 134 pg/ml (coronary artery disease) in the arterial blood, and 273 ± 152 and 250 ± 115 pg/ml, respectively, in the coronary sinus blood. Hemodynamic responses during cold stimulus were similar in both groups. Also, cold pressor-induced increases in arterial and coronary sinus l-norepinephrine contents were balanced in patients with normal coronary arteries, averaging 19 ± 30 and 17 ± 37%, respectively. In patients with coronary artery disease, however, a 26 ± 58% increase in arterial l-norepinephrine contents was associated with a 58 ± 62% increase in coronary sinus l-norepinephrine contents ($p < 0.02$), suggesting myocardial l-norepinephrine net release. It is concluded that transcardiac l-norepinephrine responses during cold stimulus are enhanced in patients with obstructive coronary artery disease. This response to a relatively mild sympathetic stress, reproducible by a variety of analogous stressful situations during daily life, could present an increased risk for acute cardiac events.

Studies during the past decade have demonstrated that sympathetic nervous activity can play an important role in the regulation of coronary blood flow. It became apparent that alpha-adrenergic–mediated coronary vasoconstriction can compete with metabolically induced coronary vasodilatation, particularly in myocardial regions with decreased coronary reserve.[1–7]

Recent studies have also emphasized that increased sympathetic nervous activity enhances ventricular irritability and lowers the threshold to ventricular fibrillation in the ischemic myocardium.[8–11] Because these observations suggest that increases in sympathetic nervous activity could place the patient with obstructive coronary artery disease at increased risk, we measured arterial and coronary sinus l-norepinephrine contents during relatively mild sympathetic stress in these patients and compared their response in transcardiac l-norepinephrine pattern with that in patients with normal coronary arteries. We selected cold pressor stimulation because it is probably similar to the level of sympathetic stress experienced frequently during daily life. Our data indicate that there is a substantially

greater increase in coronary sinus l-norepinephrine concentrations in patients with obstructive coronary artery disease than in those without disease.

Methods

Patient selection: Patients referred for heart catheterization for evaluation of angina pectoris or atypical chest pain were eligible for the study if they fulfilled the following criteria: (1) normal cardiac function as judged by clinical findings, chest x-ray, and history; (2) no medications except for a mild sedative or sublingual nitroglycerin (none 2 hours before the procedure); (3) no history or findings of hypertension (blood pressure: systolic ≥150 mm Hg, diastolic ≥95 mm Hg); (4) age under 70 years.

Procedure: Before heart catheterization, the patient was premedicated with diphenhydramine hydrochloride (Benadryl®), 50 mg intramuscularly. A #8 pigtail catheter was placed through the femoral artery into the ascending aorta and a #7 Goodale-Lubin catheter through the femoral vein into the midportion of the coronary sinus. The position of the catheter in the coronary sinus was confirmed by pressure wave form and blood oxygen tension (18 to 28 mm Hg). After placement of the catheters, the lights in the laboratory were dimmed, and conversation was kept at a minimum in an attempt to establish a "steady state." Five to 10 minutes later, left ventricular and aortic pressures were measured and aortic and coronary sinus blood samples obtained. Subsequently, the left hand of the patient, including the wrist, was immersed into a mixture of water and ice. At the onset of chest pain or of discomfort of the hand in the icewater or after 2.5 minutes of cold stimulus without symptoms, measurement of aortic pressure and sampling of aortic and coronary sinus blood were repeated. Routine left heart catheterization, including coronary arteriography, was then performed.

Blood was analyzed for l-norepinephrine and epinephrine concentrations and for oxygen tension. Ratios for myocardial l-norepinephrine uptake (extraction) or release (production were calculated by dividing the arterial-coronary sinus l-norepinephrine difference by the arterial content. Because plasma l-norepinephrine content is the net effect of neuronal l-norepinephrine release, reuptake, and metabolism,[12] the data are referred to as percentage of myocardial l-norepinephrine "net uptake" or "net release."

Determination of catecholamines: Contents of l-norepinephrine and epinephrine were measured in 1 ml of plasma with a high pressure liquid chromatograph (Waters 6000 A), using an LC-4 electrochemical detector.[13] The plasma was deproteinated, and after liquid solid extraction onto alumina, the catecholamines were eluted with 0.1 *M* $HCLO_4$. A 20 μl sample was injected into the high pressure liquid chromatograph and the individual catecholamines were separated on a μ-Bondapak C_{18} column, mobile phase (85:15 H_2O-methanol, 1% EDTA, 2 m*M* l-heptane sulfonic acid and 1% acetic acid, pH 3.8), flow rate 1 ml/min. Standards containing 200 pg/ml of l-norepinephrine and epinephrine were included along with each assay. In our laboratory, plasma catecholamine contents of 13 normal volunteers, obtained after 20 minutes of rest in the supine position, averaged 168 ± 41 (SD) pg/ml (l-norepinephrine) and 47 ± 17 pg/ml (epinephrine). The coefficient of variation of 13 duplicate determinations averaged 2.1 ± 1.5% (l-norepinephrine) and 4.5 ± 4.2% (epinephrine), respectively. The coefficients of variation of measurements, obtained at a 10-minute interval from patients before heart catheterization in the same environment as that of the patient studied, averaged 7.4 ± 5.0% and 6.8 ± 4.9% for l-norepinephrine in arterial and coronary sinus blood (n = 30) and 9.2 ± 5.8% for epinephrine in coronary sinus blood (n = 15).

Data analysis: The response to the cold pressor test within each study group was tested with a 2-tailed paired *t* test. The difference in responses between the 2 study groups was evaluated by analysis of variance with baseline values as covariates. A p value <0.05 was considered statistically significant.

Results

Patients: Twenty-three patients with normal coronary arteries, 16 male and 7 female, and 23 patients with abnormal coronary arteries, 17 male and 6 female, were

studied. The ages averaged 47 and 54 years, respectively, ranging from 31 to 65 and 30 to 67 years. The electrocardiogram was normal in all but 1 of the patients with normal and in 10 of the 23 patients with abnormal coronary arteries. Of the patients with coronary artery disease, 7 had ≥70% obstruction of 1 major dominant coronary artery, 8 patients of 2, and 8 patients of 3 major arteries. One patient had 70% stenosis of the left main stem. The left ventriculogram was normal in all patients with normal coronary arteries and showed various forms of hypokinesia or akinesia in patients with disease in segments related to the obstructed coronary artery. During cold stimulus, chest pain developed in 7 of 23 patients with coronary artery disease and was associated with depression of the S-T segment in 4 and elevation in 3. Six patients complained of chest pain without electrocardiographic changes. Two of the 23 patients with normal coronary arteries had chest pain without demonstrating other abnormalities. In 3 patients with normal coronary arteries a vagovasal reflex developed after the baseline measurements. Their results are reported separately herein.

Data on patients with normal and abnormal coronary arteries: Baseline data of the 2 patient groups are shown in Table I (mean ± SD) and Figure 1. The heart rate averaged 73 ± 15 and 76 ± 15 beats/min and aortic pressure 138 ± 20/78 ± 11 and 146 ± 20/80 ± 10 mm Hg, respectively. Left ventricular end-diastolic pressure was the only hemodynamic measurement that differed in the 2 groups; mean values were 10 ± 3.7 and 15 ± 4.5 mm Hg ($p < 0.01$). Individual data of arterial l-norepinephrine contents and of the ratios of myocardial l-norepinephrine net uptake (extraction) or net release (production) are shown in Figure 1. In all but 8 patients plasma l-norepinephrine contents were below 350 pg/ml (twice the mean value for resting normal volunteers). Five of the 8 patients with higher plasma l-norepinephrine contents had a history of a "labile nervous system" and "anxiety." The myocardial l-norepinephrine ratios (Fig. 1) varied considerably. Two thirds of the patients with normal coronary arteries demonstrated myocardial l-norepinephrine net uptake, whereas more than half the patients with coronary artery disease showed myocardial l-norepinephrine net release.

Cold stimulus by insertion of the hand into ice cold water caused changes in hemodynanic function that were similar in patients with normal and those with abnormal coronary arteries (Table I, Fig. 2). Heart rate increased an average of 10 ± 11% and 9 ± 10%, respectively, systolic pressure 21 ± 12% and 22 ± 13%, diastolic pressure 23 ± 16% and 27 ± 16%, and double product 32 ± 26% and 29 ± 16%. Increases in arterial l-norepinephrine contents, like increases in hemodynamic measurements, were similar in the 2 groups: 19 ± 30% and 26 ± 58%, respectively. In contrast, cold pressor-induced increases in coronary sinus l-norepinephrine contents differed strikingly, averaging 17 ± 37% in patients with normal and 58 ± 62% in patients with abnormal coronary arteries. Accordingly, the myocardial l-norepinephrine ratios also responded differently to cold stimulus (Fig. 3). In the normal coronary artery group cold stimulus enhanced the percentage of both myocardial l-norepinephrine net uptake and release; the mean value of the ratios remained essentially un-

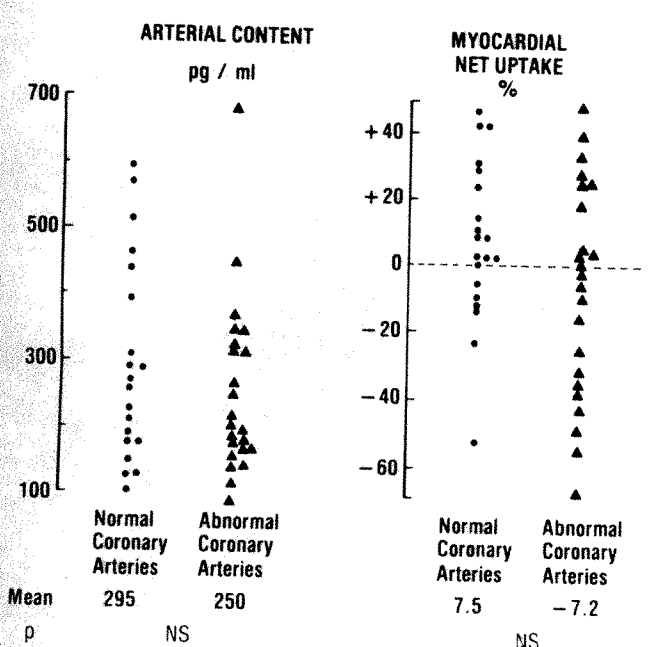

FIGURE 1. Baseline arterial l-norepinephrine contents and myocardial l-norepinephrine ratios. Arterial l-norepinephrine contents were similar in patients with normal and those with abnormal coronary arteries. Myocardial l-norepinephrine net uptake dominated in patients with normal coronary arteries, whereas l-norepinephrine net release dominated in those with abnormal coronary arteries. NS = not significant.

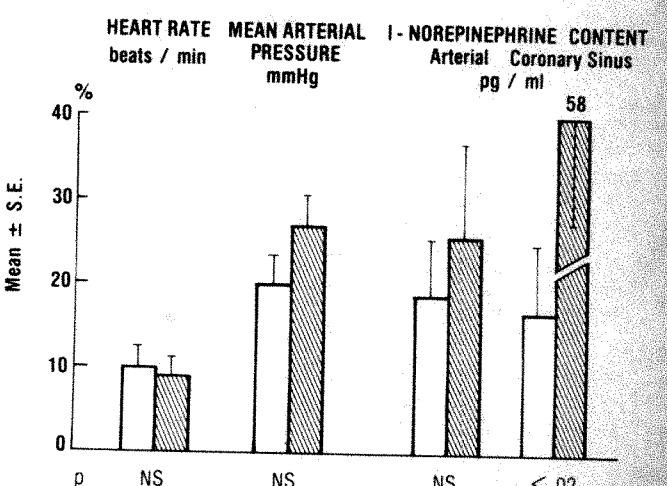

FIGURE 2. Cold pressor-induced changes in hemodynamics and plasma l-norepinephrine contents. Average increases in heart rate, mean arterial pressure, and arterial l-norepinephrine contents were similar in patients with normal (**open bars**) and those with abnormal (**hatched bars**) coronary arteries. In contrast, cold pressor-induced increases in coronary sinus l-norepinephrine contents were 3-fold higher in patients with coronary artery disease. NS = not significant.

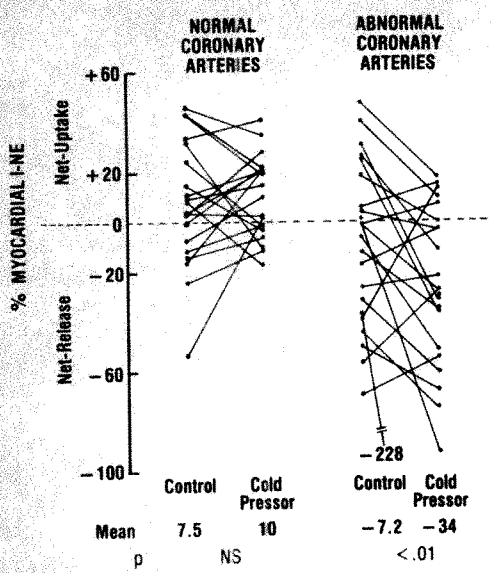

FIGURE 3. Ratios of myocardial l-norepinephrine (l-NE) net uptake (+) and l-norepinephrine net release (−). At control the majority of patients with normal coronary arteries demonstrated l-norepinephrine net uptake. The response to cold pressor varied; the mean value remained unchanged. In patients with abnormal coronary arteries myocardial l-norepinephrine net release dominated at control and was strikingly enhanced during cold stimulation. NS = not significant.

changed: 7.5 ± 29% and 10 ± 16%. In the abnormal coronary artery group, however, cold stimulus greatly enhanced the percentage of myocardial l-norepinephrine net release. Four patients had a decrease in myocardial net uptake and 14 patients had a shift from net uptake to release or enhanced l-norepinephrine net release; the mean value changed from −7.2 ± 29% to −34 ± 53% ($p < 0.01$). There was no relation between the increases in myocardial l-norepinephrine net release and the occurrence of chest pain and S-T segment changes. l-Norepinephrine net release was observed in patients with and those without findings of myocardial ischemia. Baseline arterial and coronary sinus epinephrine contents averaged about 50% above normal in both patient groups. The response to cold stimulus varied widely, and no statistically significant changes were observed.

In 3 patients with normal coronary arteries a vagovasal reflex developed after termination of the control study. The control data for arterial pressure and heart rate averaged 129 ± 8.8/85 ± 7.1 mm Hg and 98 ± 24 beats/min, respectively. During the sudden and unexpected vagovasal reflex, heart rate and arterial pressure were not recorded on paper but were observed either on the digital readout of the monitor or by blood pressure cuff. Restlessness and movement of the patient caused difficulties in obtaining the recordings. However, the heart rate decreased below 30 beats/min in all 3 patients and systolic blood pressure ranged from 40 to 60 mm Hg. After atropine, 1.0 mg intravenously, vital signs returned to normal; the mean values were 122 ± 2.8/76 ± 4.0 mm Hg and 85 ± 29 beats/min. The catecholamine response to the severe hypotensive stress during the vagovasal reflex was extensive. Plasma l-norepinephrine concentrations increased from 305 ± 100 pg/ml (control) to 973 ± 242 pg/ml in the aorta and from 264 ± 66 pg/ml (control) to 1,651 ± 353 pg/ml in the coronary sinus.

Discussion

The appearance of l-norepinephrine in blood represents a spillover from the synaptic cleft and is dependent on the level of neural stimulation, neuronal release and reuptake, blood flow, and extraneuronal metabolism.[12] Recent studies suggest that despite these limitations, plasma l-norepinephrine concentrations may be a better reflection of sympathetic neural activity than formerly believed, particularly when l-norepinephrine contents are measured across 1 specific organ. Yamaguchi et al[14] demonstrated a close relation among myocardial l-norepinephrine release, coronary blood flow, heart rate, and dP/dt during stellate ganglion stimulation in the dog; Cryer et al[15] showed in man that a prompt increase in heart rate and blood pressure after cigarette smoking was associated with a parallel increase in the l-norepinephrine contents of venous blood.

Transcardiac l-norepinephrine patterns have been studied under various conditions in man and in the experimental animal. The normal heart extracts l-norepinephrine under resting conditions.[16–20] l-Norepinephrine is released by the normal heart under conditions of substantial stress such as rapid cardiac pacing, handgrip exercise,[19–21] or stellate ganglion stimulation.[14] A vigorous noradrenergic response of the heart with a 5-fold increase in arterial and 10-fold increase in coronary sinus l-norepinephrine concentrations was observed by us in patients with normal coronary arteries and normal left ventricular function experiencing a vagovasal episode. Thus, the normal heart appears able to participate in the neurohumoral response to stress.

The ischemic heart, in contrast, releases l-norepinephrine at rest and this release may be further increased by the application of certain stresses. Handgrip[19–21] or ergometer exercise[22,23] leads to enhanced l-norepinephrine release in patients with coronary artery disease; reperfusion experiments after transient coronary occlusion in experimental animals[24–26] produce similar findings. Remarkably high concentrations of l-norepinephrine are found in coronary sinus blood in patients with acute myocardial infarction.[27]

The present study was designed to determine whether relatively mild stressful stimuli would evoke different responses in individuals with significantly obstructed coronary arteries compared with those with normal coronary arteries. Immersion of the hand in cold water—the classic cold pressor test—was selected as a stimulus that might produce a sympathetic response similar to responses experienced frequently during everyday life.

The transcardiac plasma l-norepinephrine patterns showed a major difference in the response to cold

pressor stimulation in the 2 patient populations. The mild, balanced increases in arterial and coronary sinus l-norepinephrine concentrations in the individuals with normal coronary arteries and normal cardiac function suggest a generalized sympathetic response to afferent stimuli from the periphery,[28–30] initiated from the chilled limb. A similar mild increase in arterial l-norepinephrine concentrations, but a 3-fold increase in coronary sinus concentration in those patients with obstructive coronary artery disease suggest an exaggerated response of the heart. This local cardiac response could reflect a cardiocardiac reflex as observed by Brown, Malliani, and their associates.[31–33] Transient coronary occlusion in the cat resulted in increased discharge of sympathetic afferent and preganglionic nerves associated with an increase in cardiac sympathetic activity. Changes in concentrations of hydrogen ions and potassium, hypoxia, and mechanical factors, including myocardial dysfunction,[32–35] have been suggested as mechanisms for this reflex. In the present study ischemia and impaired left ventricular function, triggered by cold stimulus, could have evoked a cardiocardiac reflex. More than half the patients with significantly obstructed coronary arteries exhibited myocardial ischemia during cold stimulus in the form of S-T segment depression, S-T segment elevation, or angina pectoris, or all 3. Left ventricular end-diastolic pressures were higher in patients with abnormal coronary arteries than in those with normal vessels so that cold stimulus-induced increases in blood pressure could have further impaired left ventricular function.[7] This possibility is consistent with the observation in patients with coronary artery disease that myocardial l-norepinephrine release during handgrip exercise was negatively related to ventricular ejection fraction[20,21] and that coronary sinus l-norepinephrine concentrations were positively related to left ventricular end-diastolic pressures.[36]

Factors other than an increase in myocardial release of l-norepinephrine might have contributed to the increase in coronary sinus l-norepinephrine concentrations during cold stimulus. l-Norepinephrine reuptake was shown to be impaired by myocardial ischemia.[37–39] In addition, cold stimulus-induced decreases of flow in diseased coronary arteries[6,7] could have exaggerated the increase in coronary sinus l-norepinephrine concentrations. The design of the study does not allow differentiation among the various mechanisms. We elected not to measure coronary blood flow in this study. Cold stimulus-triggered changes in total coronary blood flow would have been of limited value in the presence of inhomogeneity of perfusion. A decrease in venous efflux from the diseased myocardial compartment would lead to underrepresentation of abnormalities in total coronary sinus blood. Results of regional flow measurements, however, without those of regional l-norepinephrine determinations would have been difficult to interpret.

The increases in coronary sinus l-norepinephrine concentrations observed in our patients with obstructive coronary artery disease during the relatively mild sympathetic stress of cold stimulus probably occur numerous times during daily routine. Repetitive and cumulative bursts of neurotransmitter could decrease regional coronary perfusion,[3–6] increase local oxygen demand,[40] change substrate availability,[41,42] and alter the electrical properties of the myocardium.[8–11] The potential hazard of increased myocardial l-norepinephrine concentrations supports the suggestion that reducing overall sympathetic tone by antiadrenergic agents might be a useful therapeutic intervention in patients with ischemic heart disease.

In Holter studies...

An office-based system gives you the clinical data you're used to getting...without specially-trained operators.

After more than six years of development and rigorous clinical evaluation, a microcomputer based system called AEGIS™ is now available for ambulatory monitoring.

AEGIS has been designed to analyze in real time: ventricular ectopic beats (VEB), ventricular couplets (VC), ventricular tachycardia (VT), supraventricular premature beats (SVPB), and supraventricular tachycardia (SVT). Missed beats, marked pauses, sustained ventricular tachycardia, bradycardia and tachycardia are also differentiated by the system. When the 24-hour monitoring activity is completed, AEGIS provides the attending physician with a comprehensive summary report and confirming rhythm strips in minutes. The system is fully-automated so no specially-trained office staff is required, therefore turnaround time and cost of the procedure are substantially reduced.

Microcomputer Technology

The AEGIS Real Time Analyzer, a powerful 8 bit microcomputer system, combines the recording and analyzing activities in one unit that analyzes each heartbeat in real time, detecting, categorizing and counting arrhythmias as they actually occur. Because the analysis is in real time, the system is able to apply substantially more instructions per QRS than much more powerful computer systems operating at 60 to 240 times real time.

Accurate, consistent arrhythmia detection

AEGIS analyzes arrhythmias detecting departures in rate, rhythm and morphology from each patient's normal reference. The AEGIS computer can find and reference a patient's "normal" beat in less than two minutes even under a wide variety of difficult conditions such as chronic bigeminy, atrial fibrillation and bundle branch block. Furthermore, the "normal" reference beat is continually updated throughout the analysis period to account for changes in the position of the heart due to body movement.

Abnormal morphologies are detected via both feature extraction and template matching. (AEGIS is unique in its use of both methods of analysis.) When deviations exceed specified criteria, a morphology change is noted.

Rate, rhythm and morphology information is then applied to decision algorithms to determine the classification of each specific morphology change.

Overcoming problems caused by artifacts

To overcome the problem of artifacts and interference distorting information, AEGIS utilizes a series of highly refined classification algorithms developed from a data base of several hundred patients with a variety of morphologies, amplitudes and artifacts. A dual channel system, AEGIS also has the unique capability of being able to sense when artifacts are overwhelming the usefulness of information and to switch automatically to the other lead signal for processing.

Decision-making capability

The AEGIS 8 bit microcomputer system is augmented by an analog preprocessor which performs filtering, automatic gain control and QRS detection functions. Thus, the microcomputer has more time and memory available for real time decision making. In fact, AEGIS is able to apply many more computer cycles in this decision making than far more expensive scanner systems operating at high speeds.

Simplification

Because all analysis occurs within the compact 2.2 pound AEGIS Real Time Analyzer, the conventional high-speed scanner is replaced by a simple, automatic playback unit called a Report Generator. The need for a specially trained operator is eliminated.

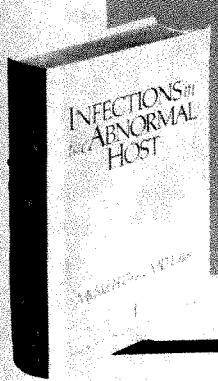
Also eliminated are the dependence of reports on the qualitative perceptions of individuals and the inaccuracies or inconsistencies that result from operator variability and fatigue.

Advantages to the physician

The AEGIS System eliminates the turnaround time involved in using a scanning service—diagnostic results are printed in the physician's office, almost immediately.

All components have built-in quality control checks for rigorous verification of the system's integrity. Patient hook-up is identical to that of conventional Holter ECG recording systems; and, with minimal training, anyone can operate the Report Generator. Once begun, the printout process requires no operator attendance and rhythm strips as well as summary categorization reports are completed in minutes.

AEGIS can significantly reduce the cost of complete Holter analysis, and since it is a software based system, the physician can keep it updated as new technological advances are made. **AEGIS Ambulatory Monitoring Systems, Medical Concepts, Inc., 137 Gaither Drive, Mt. Laurel, New Jersey 08054.**



"Clearly filled a marked gap in the infectious disease literature"[1]
"Highly recommended"[2]
"Beautifully edited, lavishly produced"[3]

Reviewers Throughout the World are Praising Dr. Grieco's New Work.

INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Prof. Clinical Medicine, Columbia Univ. College Physicians and Surgeons, Director R.A. Cooke Institute of Allergy, St. Luke's-Roosevelt Hosp., N.Y.

Text by 47 specialists, 1,035 pages, 147 illus., 78 full-color photos. Completely indexed. $79.95.

In 36 revealing chapters are reviewed the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation. INFECTIONS IN THE ABNORMAL HOST will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

1 "With this comprehensive work, Grieco has clearly filled a marked gap in the infectious disease literature. Various sections should be of interest to a broad range of practitioners . . . should serve as an important starting point and a useful reference source for any physician concerned with the complicated but increasingly important patient, the compromised host."
Philip A. Pizzo, MD, National Cancer Institute, **NEW ENGLAND JOURNAL OF MEDICINE**, Jan. 8, 1981

"This work will serve the physician well in caring for patients with serious infections. It is well organized and easy to use for quick reference. It also serves as an extensive review of infections in the defective host for specialists in infectious disease, pulmonary medicine, and cancer."
W. Lee Fanning, MD, **JOURNAL AMERICAN MEDICAL ASSOCIATION**, Jan. 2, 1981

"This important text should play a valuable role in the understanding and management of infections in the abnormal host and shows how clinical microbiologists, immunologists, and infectious disease clinicians can work together in the diagnosis and management of patients."
D.M. Weir, Dept. Bacteriology, Univ. of Edinburgh, **LANCET**, July 19, 1980

2 "This book is expertly edited . . . an outstanding feature is the thoroughness in which the book is indexed . . . As a comprehensive text for the academician and as a sound guide for the clinician in every field, the book is highly recommended. Immunologists, microbiologists, oncologists, internists, and specialists in infectious diseases should either purchase the book or have a copy readily available as a reference. Medical and graduate school libraries should own copies."
E.A. Gorzynski, **IMMUNOLOGICAL COMMUNICATIONS**, Sept. 7, 1980

3 "And so we must not only choose the correct antibiotic but also overcome the infection in this compromised, immunosuppressed patient or what we commonly term the person with poor resistance. This clearly calls for a book of guidance and this is it, all 1,035 pages of it, beautifully edited, lavishly produced, and with the experience and wisdom of 47 contributors."
D. Geraint James, FRCP, Dean Royal Northern Hospital, London, **MILAN DAILY MEDICAL NEWSPAPER**, May 1980

YORKE MEDICAL BOOKS, Box C-757, Brooklyn, N.Y. 11205

Please send, on approval, ____ copies of INFECTIONS IN THE ABNORMAL HOST, edited by Michael H. Grieco. I will be free to read and consult the book in any and all relevant situations for 30 days. If I am not convinced it is a valuable professional tool, I will return it and owe nothing. Otherwise, I will remit $79.95 plus shipping.

Send invoice, plus shipping.

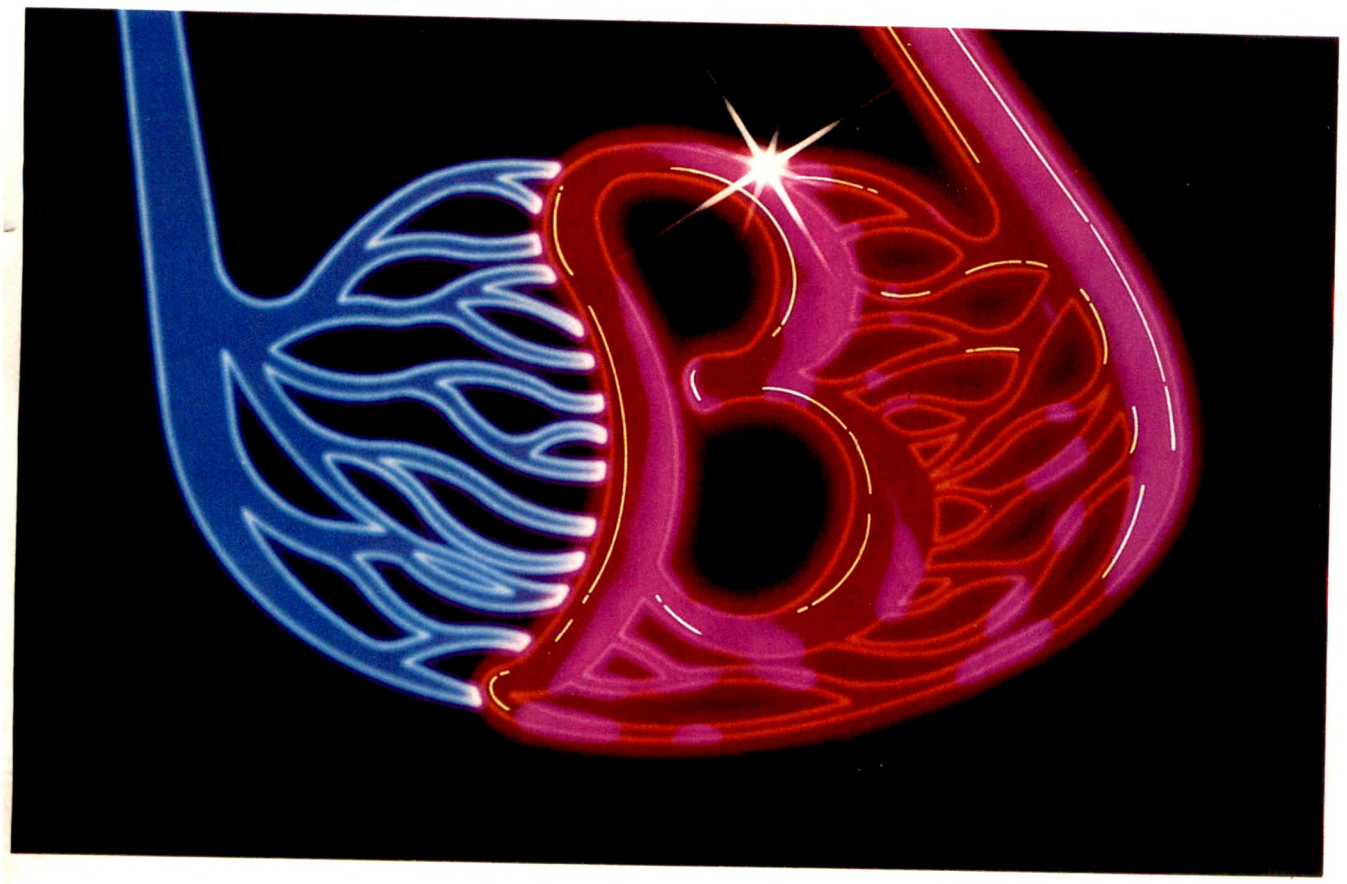
New York residents add applicable sales tax. Countries outside Western Hemisphere add $5.00 per copy.

AJCL2



Pick the only beta blocker that reduces total peripheral resistance:

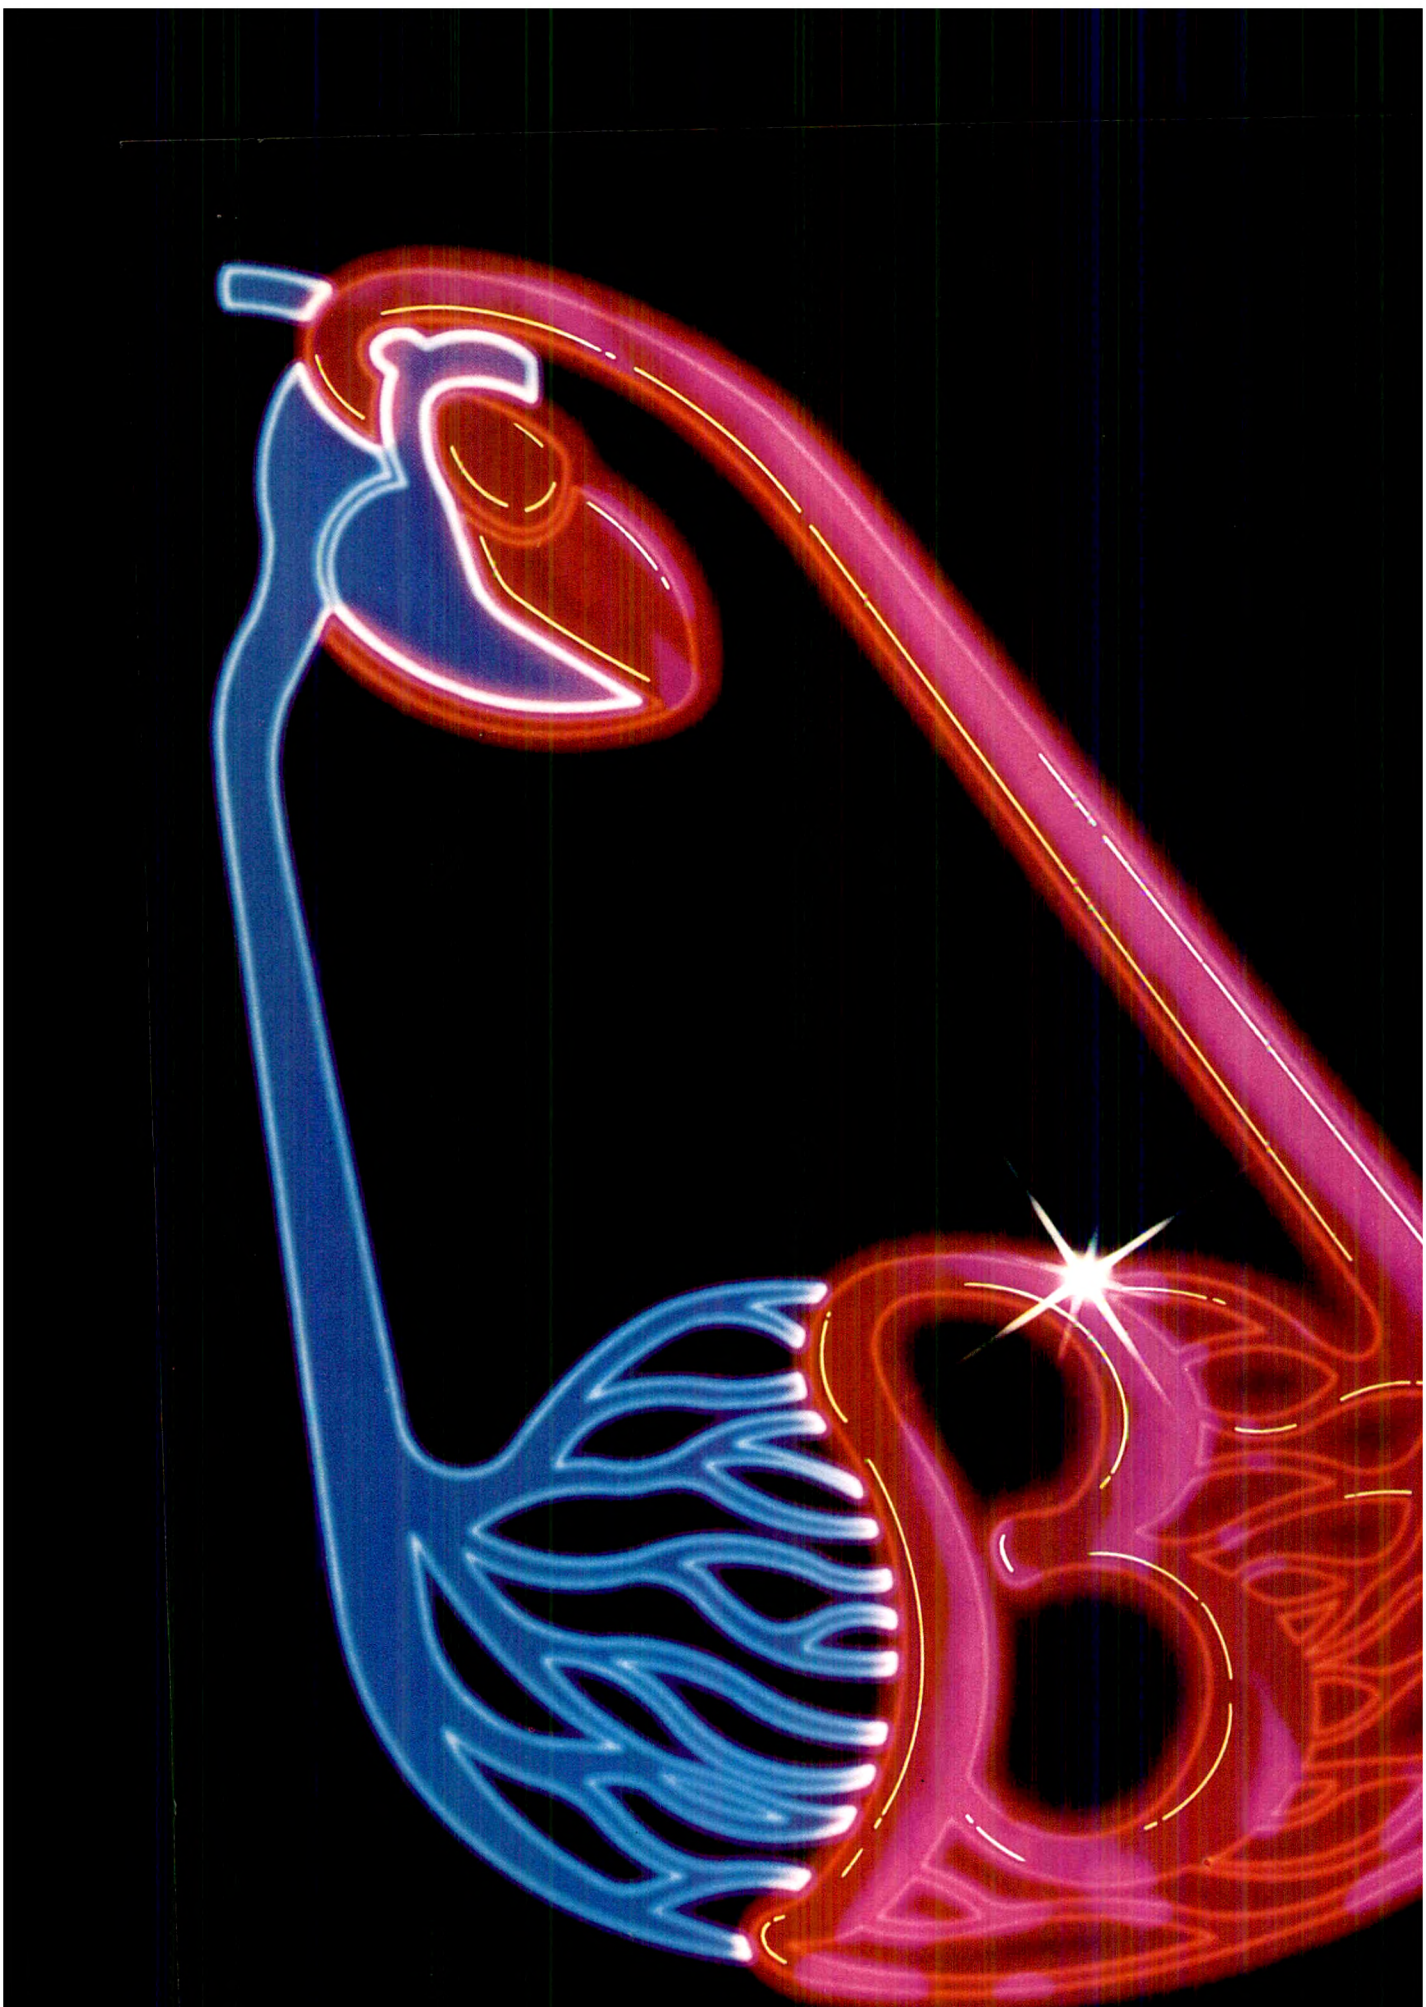
1. Inderal® (propranolol)

2. Lopressor® (metoprolol)

3. Tenormin® (atenolol)

4. None of the above

(If you picked #4, you're right.)



Introducing:

Visken® (pindolol)

the only beta blocker that reduces blood pressure and total peripheral resistance

Here's the difference:

Blood pressure

Blood pressure equals cardiac output times total peripheral resistance.

$$bp = co \times tpr$$

Visken (pindolol)

Visken (pindolol) is the only beta blocker that reduces blood pressure while maintaining resting cardiac output and reducing total peripheral resistance during long-term therapy.

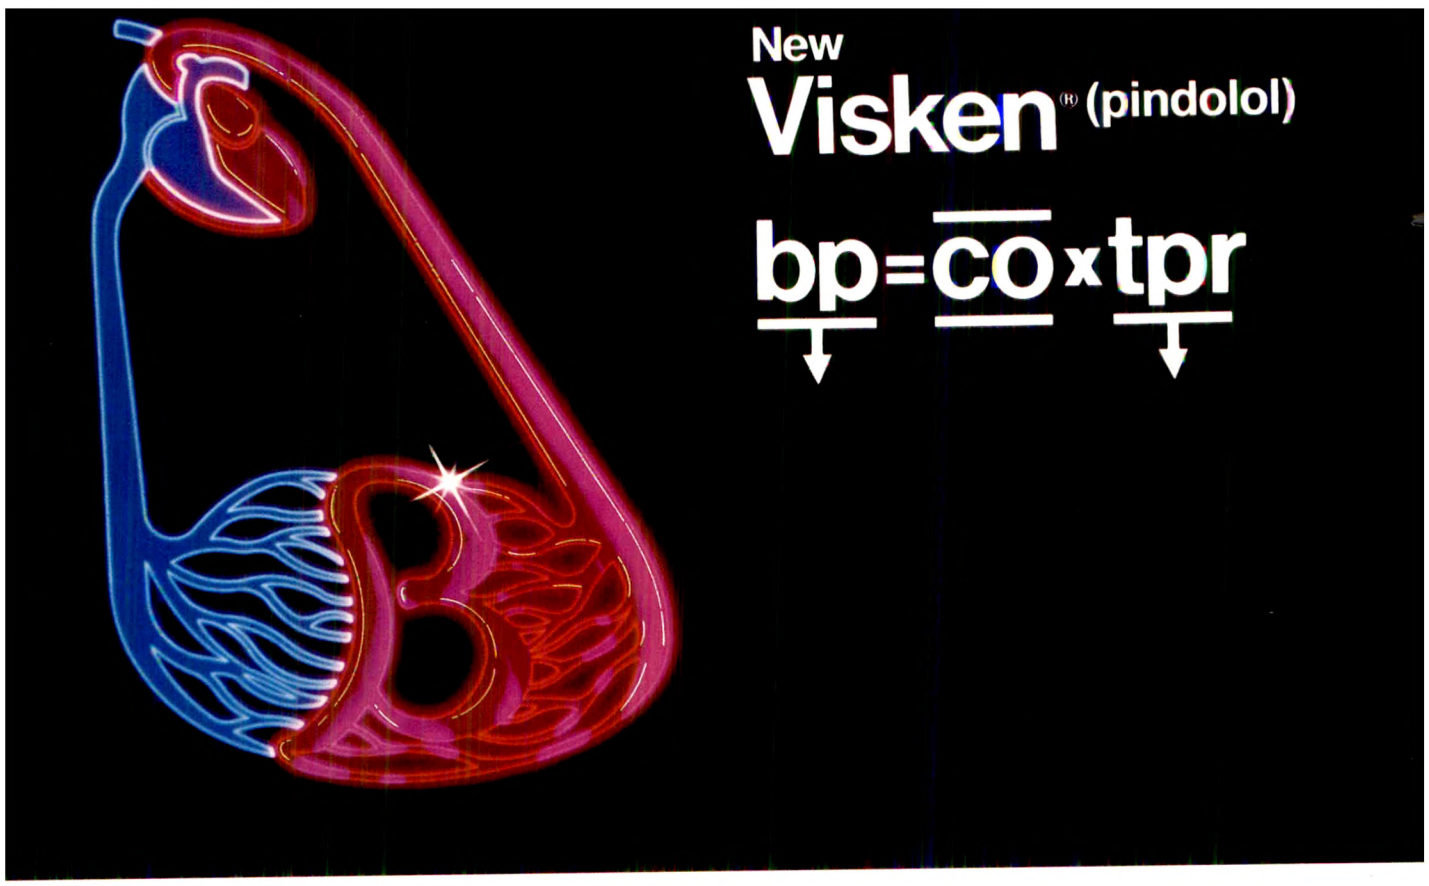
$$\underline{bp} = \underline{\overline{co}} \times \underline{tpr}$$

All other beta blockers

All other beta blockers reduce blood pressure, and reduce cardiac output with an initial reflex rise in total peripheral resistance and a subsequent return to baseline in many cases.

$$\underline{bp} = \underline{co} \times \overline{tpr}$$

Please see last page of this advertisement for brief summary of prescribing information.



Here's the result:

Reduced blood pressure

U.S. studies at 29 major medical centers[1] have shown that Visken (pindolol) is an effective antihypertensive. It is as effective as propranolol in normalizing blood pressure (dbp≤90 mmHg) when used alone. It is also effective when used in combination with a diuretic.

This antihypertensive effectiveness is supported by 13 years of clinical use throughout the world. In fact, Visken (pindolol) is the #2 beta blocker in the rest of the world.

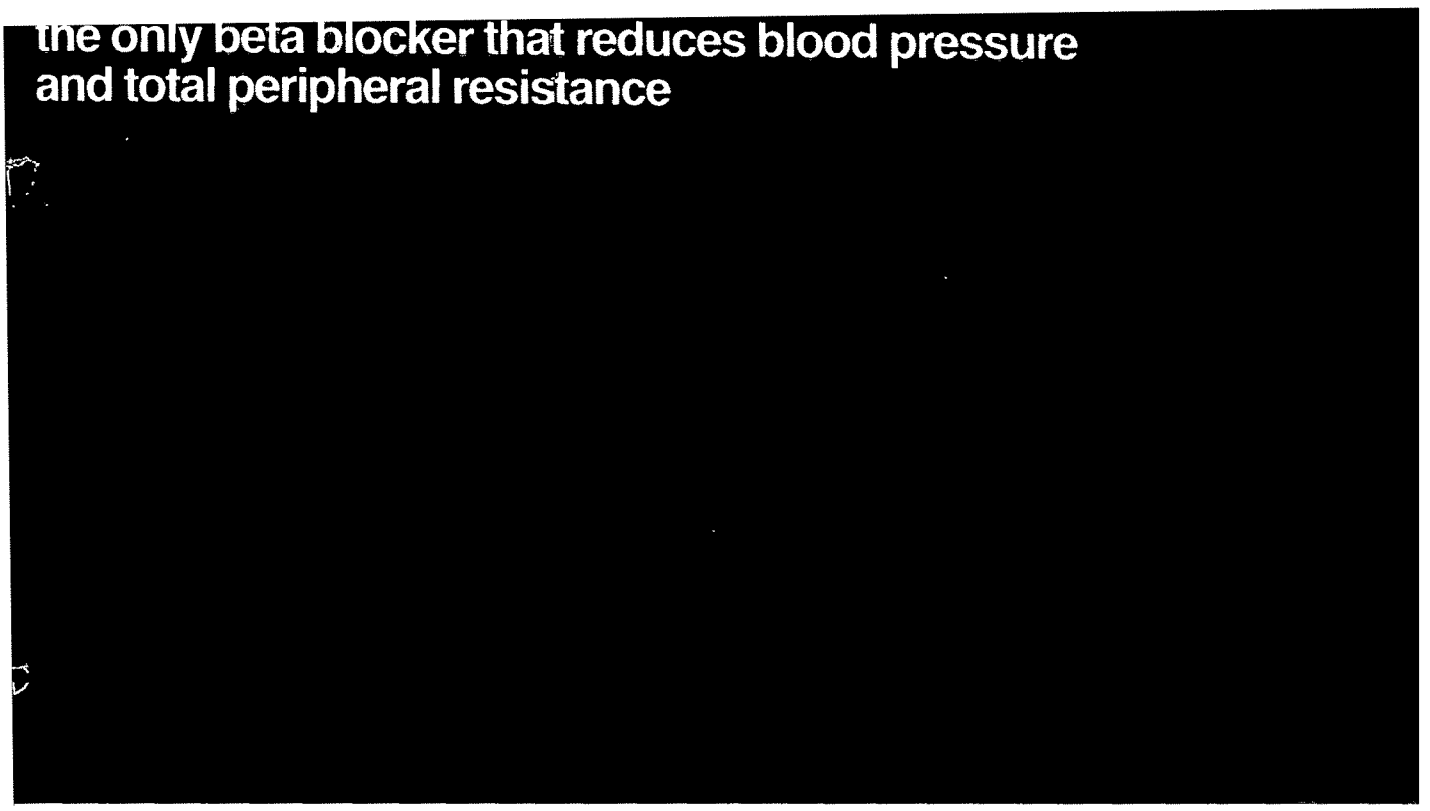
Reduced peripheral resistance

Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

Reduction of exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

the only beta blocker that reduces blood pressure and total peripheral resistance



Here's the importance:

Visken® (pindolol) makes hemodynamic sense in the treatment of hypertension

Visken (pindolol) treats the basic abnormality of hypertension: increased peripheral resistance.

Visken (pindolol) reduces blood pressure with little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) has little effect on resting cardiac output during long-term therapy. The clinical significance of this observation has not been evaluated.

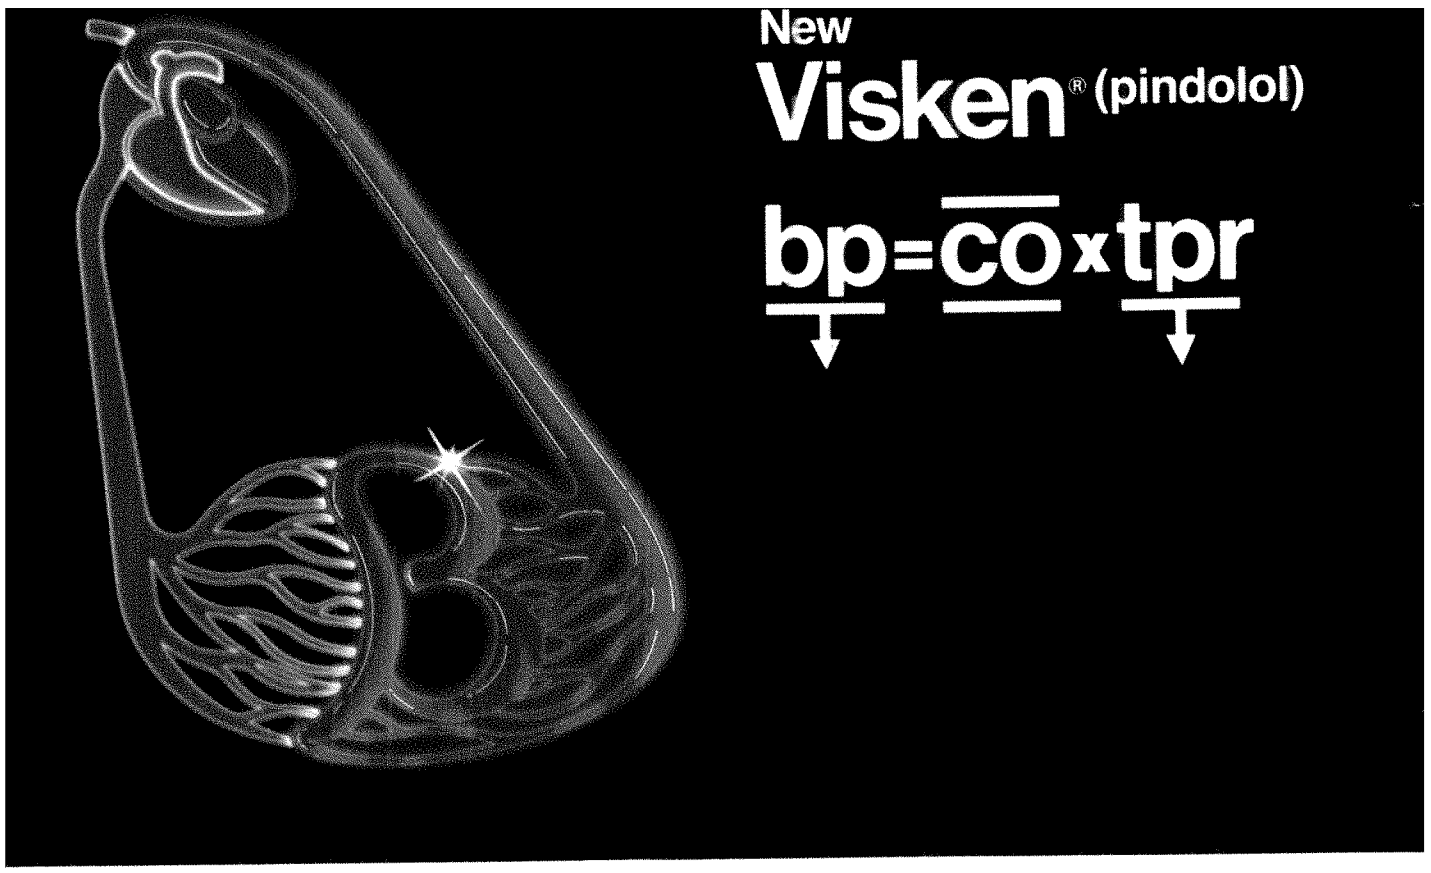
Visken (pindolol) reduces blood pressure with little effect on resting heart rate

Visken (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute. Minimal effect on resting heart rate results in low potential for bradycardia.

Visken (pindolol) maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

See last page of this advertisement for brief summary of prescribing information.



Here's what you can expect:

Reduced total peripheral resistance

Minimal effect on resting cardiac output

Minimal effect on resting heart rate

Minimal effect on renal blood flow

Favorable side effect profile*

Low incidence of bradycardia

Low incidence of cold extremities

* Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

Prescribing information:

Available in 5 mg and 10 mg tablets

Convenient bid dosage

Dosage should be titrated on an individual basis. Many patients respond to 10-30 mg a day in divided doses.

Please see last page of this advertisement for brief summary of prescribing information.

New Visken® (pindolol)

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of β_2 receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elicited) Visken (pindolol) (N = 322) %	Active Controls* (N = 188) %	Placebo (N = 78) %

*Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting. RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with chills and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and nonthrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a beta$_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 5 mg b.i.d. alone or in combination with other antihypertensive agents. Many patients will respond to 15 mg per day (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactory reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 mg per day at 2-3 week intervals up to a maximum of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packaged in bottles of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05).

The QT $>QS_2$ Syndrome: A New Mortality Risk Indicator in Coronary Artery Disease

HARISIOS BOUDOULAS, MD, YOUNG HO SOHN, MD, WILLIAM O'NEILL, MD, ROGER BROWN, BS, and ARNOLD M. WEISSLER, MD

In the normal population the duration of electrical systole (QT) is shorter (mean −26 ± 13 ms, 1 standard deviation) than that of electromechanical systole (QS_2), which it closely parallels throughout the range of resting heart rate. This close association prompted the hypothesis that the duration of QT may be more closely linked physiologically to QS_2 than to the heart rate and hence may provide a more potent prognostic indicator than the relation of QT to heart rate. The present study was designed to test this hypothesis. One hundred stable patients 14 months after myocardial infarction were followed up an average of 43 months. Twenty patients had prolongation of QT relative to QS_2 (QT $>QS_2$) and 13 patients had long QT corrected for heart rate (QTc). There were 20 deaths (16 sudden). The cumulative 5 year survival rate was 35% in patients with QT $>QS_2$ and 91% in patients with QT $\leq QS_2$ ($p < 0.001$). There was no significant difference in survival in patients with long QTc compared with patients with normal QTc (69 versus 82%). Univariate and multivariate analysis for the association of QT $>QS_2$ with known risk factors, clinical descriptors, drug therapy, systolic time intervals (preejection period/left ventricular ejection time), and frequency of 1, 2, and 3 vessel coronary occlusive artery disease revealed that only the presence of abnormal preejection period/left ventricular ejection time added significantly to the presence of QT $>QS_2$ in stratifying 5-year survival into high and low risk groups. Thus, in patients with coronary artery disease, the presence of QT $>QS_2$ provides a new risk indicator that is more potent than QT corrected for heart rate.

Prolongation of electrical systole (QT) is associated with a high incidence of ventricular arrhythmia and sudden death in patients with and without coronary artery disease.[1–5] Traditionally, the heart rate is employed for correcting the duration of electrical systole and hence for identifying patients with prolongation of the QT interval.[6–8] Recent studies from our laboratory have demonstrated that the duration of the QT interval in normal persons is consistently shorter and closely parallels the duration of electromechanical systole (QS_2) throughout the normal range of resting heart rate.[9,10]

From the Department of Medicine, Wayne State University, and Harper-Grace Hospitals, Detroit, Michigan, and the Cardiovascular Center, Veterans Administration Medical Center, Allen Park, Michigan. This work was supported in part by a grant from the Veterans Administration Research Advisory Group and Harper-Grace Hospitals, Allen Park and Detroit, Michigan. Manuscript received February 9, 1982; revised manuscript received June 1, 1982, accepted June 16, 1982.

Address for reprints: Harisios Boudoulas, MD, Division of Cardiology, Veterans Administration Medical Center, Allen Park, Michigan 48101.

The close association between the duration of the QT and QS_2 intervals prompted the hypothesis that QT may be more closely linked physiologically to the duration of electromechanical systole than to heart rate. The relation of the QT to the QS_2 interval may therefore provide a more pertinent reference standard for defining lengthening of the QT than the traditional correction for heart rate. If this hypothesis is correct, the relation of the QT interval to QS_2 should provide a more sensitive measure of QT prolongation and hence be a more potent prognostic indicator than the relation of the QT interval to heart rate. The present study was undertaken to test this hypothesis in patients with established coronary artery disease.

Methods

One hundred consecutive patients with stable coronary artery disease after previous myocardial infarction who were admitted for coronary arteriography were selected as subjects for this study between January 1974 and December 1977. The

reference myocardial infarction occurred an average of 14 months (standard deviation [SD] 2 months) before determination of the duration of electrical and electromechanical systole. Average follow-up time was 43 months (standard deviation 18 months), with a minimal follow-up period of 24 months. Patients with valvular heart disease, left intraventricular conduction defect, recent myocardial infarction (<3 months), and noncardiac diseases that might independently affect survival or did not allow clear detection of the temporal landmarks for measuring the pertinent intervals were excluded before selection of the patients for prospective study.

Noninvasive determinations were performed within 48 hours of diagnostic coronary arteriography. Noninvasive measures were obtained with the patients resting in the supine position and measurements were made without knowledge of the arteriographic observations. No patient in this study experienced typical angina pectoris or precordial discomfort during recording of the nonivasive measures.

The duration of electrical systole (QT) and that of electromechanical systole (QS_2) were measured from a simultaneously recorded phonocardiogram and electrocardiogram at a paper speed of 100 mm/s. The standard electrocardiographic lead best delineating the onset of QRS and a clear inscription of the T wave was selected for measurement of the QT interval. The QT interval was measured from the beginning of the Q wave to the termination of the T wave at the point of its merger with the T-P segment.[10,11] When the end of the T wave was not precisely delineated, its termination was taken as the point where the line of most rapid descent of the T wave transected the baseline between the T wave and the upstroke of the subsequent P wave.[11] When a T wave <3 mm was not apparent and a U wave interfered with the definition of the T wave, the patient was not entered in the study. A microphone (EFM contact microphone, frequency range 100 to 500 H was placed over the second left intercostal space in the parasternal area so that the aortic and pulmonary components of the second sound could be clearly distinguished. The QS_2 interval was measured from the onset of ventricular depolarization as delineated in a sharp Q wave, on a standard lead, to the first high frequency vibration of the aortic component of the second heart sound. The aortic component of the second heart sound was identified by observation of the normal respiratory pattern in the components of the second heart sound and by their temporal relation to the incisural notch on a simultaneously recorded carotid arterial pulse tracing. The aortic component of the second heart sound was taken as those high frequency vibrations that consistently preceded the incisural notch throughout the respiratory cycle. The measurements were obtained from at least 10 consecutive cardiac cycles which were averaged to obtain the mean QS_2 and QT. The QT minus the QS_2 ($QT - QS_2$) for each patient was calculated from this mean value. Because there is no temporal delay in recording the QT and QS_2 intervals, the $QT - QS_2$ can be measured alternatively as the interval from the end of the T wave to the onset of the aortic component of the second heart. All temporal measurements were expressed in milliseconds.

Among 50 normal subjects the QT interval was consistently shorter than the simultaneously measured QS_2 interval. The $QT - QS_2$ followed a Gaussian distribution with a mean of -26 ms ± 13 (1 SD). Lengthening of the QT relative to the QS_2 by 2 SD above the mean for the normal population was defined as abnormal lengthening of the QT relative to the QS_2 ($QT > QS_2$). Hence, any value of $QT - QS_2 > 0$ was considered abnormal. The patients were divided into 2 groups: those with a normal QT relative to QS_2 ($QT \leq QS_2$, n = 80) and those with a lengthened QT relative to QS_2 ($QT > QS_2$, n = 20). The QT was corrected for heart rate (QTc) employing the conventional Bazzett equation, $QTc = QT\sqrt{RR}$. The normal QTc averages 0.39 for male subjects and 0.415 for female subjects.[6] The range of normal about the mean QTc for each sex is the mean value ±0.04 as defined by Bazzett. Hence, any value of QTc >0.43 in the male or >0.455 in the female was considered abnormal. For each patient the QT was calculated as the mean of measurements made on the same consecutive beats as those used to calculate the QS_2. Four additional corrections based on various equations relating heart rate and QT interval were employed in detecting QT prolongation.[7,9,12,13]

To test the influence of electrocardiographic lead-to-lead variation on the $QT - QS_2$, the intervals were measured in 7 normal control subjects for 12 simultaneously recorded electrocardiographic leads. Only leads demonstrating clear delineation of the termination of the T wave were employed in the analysis. No significant lead-to-lead variation in $QT - QS_2$ was present (mean variation irrespective of sign 2.4 ms, SD 3 ms for 7 subjects). In calculating the interval $QT - QS_2$, the QRS duration is subtracted (QRS is a constant in both the QT and QS_2 intervals). Therefore, the duration of the ST-T component of the QT interval is the critical determinant of variations in the QT relative to QS_2.

In 5 patients with $QT > QS_2$, $QT - QS_2$ measurements were performed on more than 1 occasion at 1 month intervals. In each patient, consistent prolongation of QT relative to QS_2 was demonstrated on the repeated determinations.

Systolic time intervals were measured as previously described in our laboratory.[14,15] The QS_2 was corrected for heart rate (QS_2I) according to previously published linear regression data ($QS_2I = QS_2 + 2.1$ heart rate for male subjects and $QS_2I = QS_2 + 2.0$ heart rate for female subjects).[15] QS_2I followed a Gaussian distribution in normal subjects. The normal range of QS_2I was hence considered to be in the 2 standard deviation range. By this definition a QS_2I less than 518 ms for male subjects and less than 520 ms for female subjects was considered abnormally abbreviated. The ratio of the preejection period (PEP) to the left ventricular ejection time (LVET) was employed in defining left ventricular performance. In previous studies, this measure has proved as accurate an expression of left ventricular global performance as the left ventricular ejection fraction, determined by contrast ventriculography, in patients with coronary artery disease.[16–18] The normal PEP/LVET is 0.34 ± 0.04 (1 SD). A PEP/LVET of 0.42 was considered the upper (2 SD) limit of normal for both sexes.

Selective coronary cinearteriography was performed in all patients employing the Sones or Judkins technique. The degree of coronary arterial narrowing was assessed without knowledge of other invasive or noninvasive data by 2 of us who reached consensus as to the number of arteries involved with ≥70% luminal area narrowing (≥50% diameter narrowing).

Cumulative 5-year survival curves were calculated for patient groups divided according to (1) presence or absence of $QT > QS_2$, (2) presence or absence of QTc prolongation, and (3) presence or absence of QS_2I shortening. Because left ventricular performance is a major independent determinant of prognosis in patients with coronary artery disease, patients with and without $QT > QS_2$ were further subdivided into those with normal left ventricular performance (PEP/LVET ≤0.42) and those with abnormal left ventricular performance (PEP/LVET >0.42). In addition, the extent of arterial occlusive disease was compared for patients subgrouped according to the presence or absence of $QT > QS_2$. The cause of death in each patient was determined by interview with close

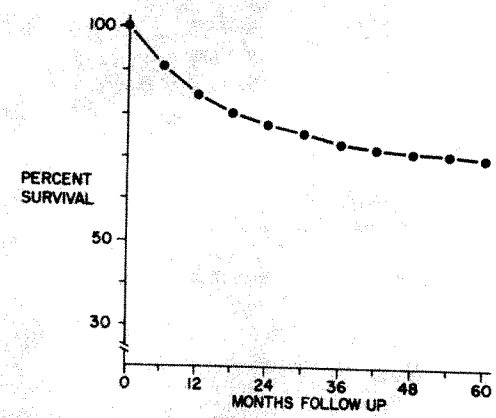

FIGURE 1. Cumulative 5-year survival rate after QT and QS_2 determination for the entire series (100 patients).

relatives and physicians and review of hospital charts. Sudden death was considered to be death within 1 hour of onset of symptoms or death before reaching medical care.

Risk factors, clinical descriptors, and drug therapy were considered individually to determine whether there were significant differences among the patients with and without QT >QS_2. For this analysis the standard 2 sample t test was employed for continuous data, whereas the distribution of dichotomous variables (chi-square test) was employed for discrete data. Each risk factor and clinical descriptor was also studied by univariate analysis for its capacity to discriminate differences in cumulative 5-year survival.[19,20] Those risk factors and clinical descriptors subjected to analysis were age, sex, arterial blood pressure, serum cholesterol, history of smoking, family history of coronary artery disease, history of diabetes, history of myocardial infarction before the reference myocardial infarction, New York Heart Association class for dyspnea, New York Heart Association class for angina pectoris, presence of S_4 gallop, presence of S_3 gallop, and electrocardiographic location of myocardial infarction. S_4 and S_3 gallops were considered present only when confirmed by phonocardiography. The administration of the following drug groups during the follow-up period was analyzed: diuretics, beta-blocking agents, nitrates, and antiarrhythmic agents. The following were considered the upper limit of normal in univariate survival analysis: serum cholesterol 250 mg/dl, and systolic arterial blood pressure 150 and diastolic 90 mm Hg. A smoking history was positive if the patient had smoked 1 or more packs of cigarettes per day for more than 1 year during 10 years before entering the study.

Variables found to be significantly different between the groups with and without QT >QS_2 by t test or chi-square analysis and those found to provide significant prognostic information by univariate life table analysis were subjected to multivariate analysis by the proportional hazards general linear model procedure developed by Mantel,[20] Peto,[21] and Harris et al.[22] The strategy of this multivariate analysis permits identification of predictors of survival after adjustment for the effects of other risk factors and thus affords an approach to the analysis of the contribution of associated risk variables to the prognostic potency of the QT >QS_2 in the same group of patients.

Results

Death occurred in 20 of the patients during the follow-up period. The cause of death was sudden in 16, congestive heart failure in 2, and recurrent myocardial infarction in 2. Among the nonsurvivors the incidence of QT >QS_2 (65%) was significantly greater than that among survivors (9%) ($p < 0.01$). Among the nonsurvivors the incidence of long QTc (20%) did not differ significantly from that among survivors (11%).

The 5-year cumulative survival curve for the entire patient group is shown in Figure 1. The overall survival for the group was 80%, corresponding to a cumulative mortality rate of 20%.

Twenty patients had QT >QS_2 and 80 patients had QT ≤QS_2. The cumulative 5-year survival curves for these groups are shown in Figure 2. The cumulative 5-year survival for patients with QT >QS_2 (35%) was significantly diminished compared with that for patients with QT ≤QS_2 (91%) ($p < 0.001$).

The cumulative survival curves for the 87 patients with normal QTc (Bazzett) and the 13 patients with prolonged QTc are shown in Figure 3. The cumulative survival in patients with increased QTc was slightly but not significantly lower than that of patients with normal

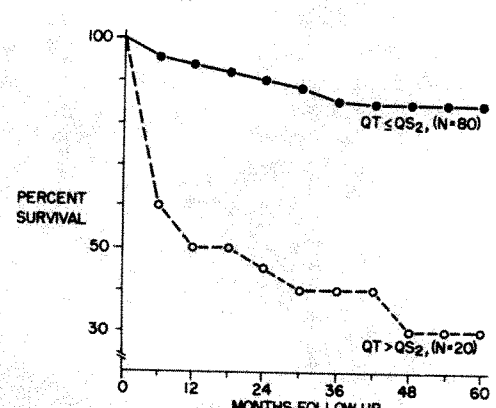

FIGURE 2. Cumulative 5-year survival rate for patients with and without QT >QS_2. The difference in survival curves is significant ($p < 0.001$).

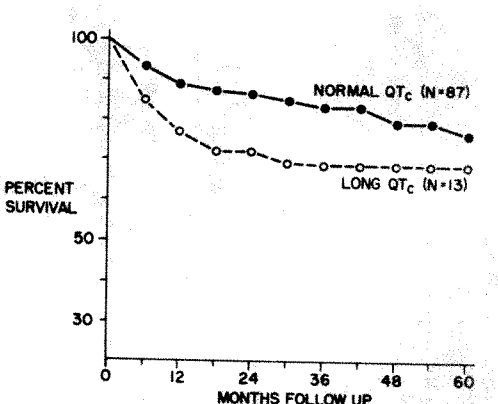

FIGURE 3. Cumulative 5-year survival rate for patients with normal and long electrical systole corrected for heart rate (QTc). The difference in survival curves is not significant.

QTc. Other equations for correcting the QT for heart rate were similarly less sensitive in stratifying the population into low and high risk groups (Table I).

Eleven patients had decreased total electromechanical systole corrected for heart rate (QS_2I), whereas 89 patients had normal QS_2I. The cumulative survival data for patients with normal or decreased QS_2I are shown in Figure 4. Survival in patients with decreased QS_2I

was slightly but not significantly lower than that of patients with normal QS_2I. Thus, although determination of QT >QS_2 stratified the patients into 2 distinct survival patterns, neither the QTc nor the QS_2I alone could significantly distinguish patients with high or low risk of mortality.

To define the relative contribution of QT lengthening and QS_2 shortening to the presence of QT lengthening relative to QS_2, patients with QT >QS_2 were analyzed relative to the distribution of QTc and QS_2I (Fig. 5). Among the 20 patients with QT >QS_2 the levels of QTc tended to cluster within the upper range of normal, whereas the QS_2I decreased within the lower range of normal. Abnormal lengthening of QTc occurred in 7 of the patients with QT >QS_2, whereas abnormal shortening of QS_2I occurred in 5. Therefore, the presence of QT >QS_2 proved to be a result of the combined influence of QT lengthening and QS_2 shortening without a dominant influence of either variable.

Univariate analysis for the significance of differences in risk factors and clinical descriptors among patients with and without QT >QS_2 is shown in Table II. The 2 variables that retained significant difference in the 2 groups were the PEP/LVET and the mean number of coronary arteries with >70% narrowing. Independent univariate survival analysis for each of these risk factors and clinical descriptors demonstrated that the same 2 variables in addition to QT >QS_2 had significant independent prognostic value. Comparison of the survivors with the nonsurvivors with respect to each of these risk factors and clinical descriptors demonstrated significant differences for the presence of QT >QS_2, ab-

normal PEP/LVET, dyspnea class, therapy with diuretics, and therapy with beta-blocking agents (Table III). Multivariate analysis by the proportional general linear hazards model revealed that of the foregoing variables, only PEP/LVET added significantly to the potential value of QT >QS_2 in stratifying the cumulative 5-year survival curves.

To further test the relative potency of the 2 variables, left ventricular resting performance by PEP/LVET and the occurrence of QT >QS_2 as survival predictors, the patients were divided into groups with normal and abnormal PEP/LVET and subdivided for the presence of QT >QS_2. Among the 47 patients with normal PEP/LVET only 4 had QT >QS_2, thus precluding accurate comparison of survival stratification by QT >QS_2 in this group. Among the 53 patients with abnormal PEP/LVET the group with QT >QS_2 (16 patients) was sufficiently large to allow a test of the independent influence of PEP/LVET and QT >QS_2 on survival. The data are summarized in Figure 6. Cumulative 5-year survival of patients with abnormal PEP/LVET and QT >QS_2 was significantly lower compared with that of patients with abnormal PEP/LVET in the absence of QT >QS_2 ($p < 0.01$). The average PEP/LVET and the mean number of coronary arteries with >70% narrowing did not differ significantly in these 2 groups (Table IV).

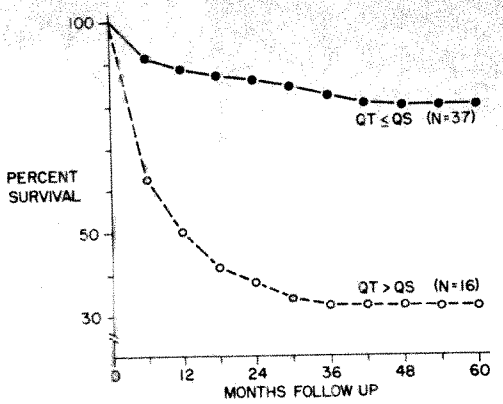

FIGURE 6. Cumulative 5-year survival rate for patients with abnormal left ventricular performance (preejection period/left ventricular ejection time, >0.42) with and without QT >QS_2. The difference in survival curves is significant ($p < 0.01$).

Discussion

In recent studies we demonstrated that measurement of systolic time intervals permits stratification of patients with previous myocardial infarction into widely divergent survival groups.[23] The cause of death among patients so stratified was dominantly sudden death. The prognostic potency of the systolic time interval measurement was greater than that of the extent of coronary arterial narrowing. These studies were consonant with those of Gillilan et al,[24] who similarly demonstrated a high level of stratification of patients with coronary artery disease into low and high risk groups by the measurement of systolic time intervals. On this basis, we focused attention on the potential value of additional noninvasive measures that might sensitize the prognostic potential of the systolic time intervals. Among these was the duration of electrical systole, the subject of the present investigation.

The current study documents that the presence of QT >QS_2 constitutes a significant risk factor in patients who have recovered from previous myocardial infarction. Further, it was documented that the use of the QS_2 as a normative reference lends a more sensitive prognostic index than that provided by equations that correct the QT interval for heart rate.

Analysis of the contribution of risk factors, clinical descriptors, and drug therapy in coronary artery disease to survival differences associated with normal and increased QT relative to QS_2 is pertinent to the question: does the presence of QT >QS_2 constitute an independent risk factor or is it a measure closely associated with other factors known to influence survival in coronary artery disease? Only 2 variables, the exent of coronary arterial occlusive disease and the presence of left ventricular dysfunction, proved significantly different among patients with and those without QT >QS_2. Each of these proved to be independent risk discriminators on 5-year cumulative survival analysis as well. When these 2 variables were compared with QT >QS_2 by proportional general linear analysis, only PEP/LVET added significantly to the QT >QS_2 in stratifying the cumulative 5-year survival curves.

An increase in the QT interval normalized for QS_2 yields a more direct expression of prolongation of the repolarization phase of electrical systole than can be derived from determinations of the QT interval corrected for heart rate. In calculating the difference between the durations of the QT and QS_2 intervals in the same beats, the duration of the QRS interval, a constant in both measures, is subtracted. In correcting the duration of the QT interval relative to heart rate, the QRS

TABLE IV Extent of Vessel Disease in Patients With and Without QT >QS_2 Subdivided for Presence of Left Ventricular Dysfunction

	PEP/LVET ≤0.42			PEP/LVET >0.42		
	QT >QS_2 (n = 4)	QT ≤QS_2 (n = 43)	p	QT >QS_2 (n = 16)	QT ≤QS_2 (n = 37)	p
Vessels*	1.75 ± 0.96	1.67 ± 0.75	NS	2.3 ± 1.1	2.10 ± 0.80	NS
Mean PEP/LVET	0.36 ± 0.03	0.37 ± 0.04	NS	0.53 ± 0.02	0.52 ± 0.02	NS

* Number of vessels with luminal narrowing of >70%. Values are expressed are mean ± standard deviation.

interval is included and contributes independently to the duration of the corrected or normalized QT interval. Thus, assessment for the presence of a prolonged repolarization phase by normalization for heart rate is limited by the inclusion of the duration of the depolarization interval in the calculation.

Prolongation of the QT interval as defined by its relation to the QS_2 interval might be accounted for by abbreviation in the QS_2 interval alone. Such a selective shortening of QS_2 relative to QT has in fact been observed during adrenergic stimulation of the heart, an effect that is blocked by propranolol.[10] However, the presence of QT >QS_2 among patients in this study was related to the coexistence of a relative lengthening of QT and a shortening of QS_2. Because increased adrenergic activity tends to selectively shorten the QS_2 interval with little influence on the QT,[10] it appears that enhanced adrenergic cardiostimulatory activity alone cannot explain the occurrence of QT >QS_2.

Among other mechanisms that may account for relative prolongation of electrical systole, localized or generalized delay in intramyocardial repolarization secondary to ischemic myocardial damage, autonomic factors, central nervous system influences, and antiarrhythmic drug therapy must also be considered. The role of the first 3 of these mechanisms was not elucidated in the present study. Regarding antiarrhythmic therapy, there was no significant difference in such therapy among patients with and those without QT >QS_2. On separate analysis there was no significant difference in antiarrhythmic therapy when survivors and nonsurvivors of the present study were compared.

In summary, our observations demonstrate that detection of prolongation of the QT interval, and more specifically of the repolarization phase of electrical systole employing the duration of electromechanical systole (QS_2) as a standard of reference, clinically defines a group of patients with prior myocardial infarction at hish risk of death. The QT interval corrected for the QS_2 is superior to the QT corrected for heart rate as a prognostic indicator. The improved prognostic potency of the QT interval corrected for QS_2 most probably reflects a more direct physiologic link between electrical repolarization and mechanical events of the cardiac cycle. The exact mechanism through which chronic ischemic heart disease contributes to prolongation of the QT interval relative to mechanical systole has yet to be defined. Although adrenergic influences may contribute, they cannot wholly explain the presence of QT >QS_2 among patients at high risk. Other factors probably play a significant role. The association of this finding with other indexes of electrical instability has yet to be defined.

Transaxial Tomography With Thallium-201 for Detecting Remote Myocardial Infarction

Comparison With Planar Imaging

JAMES L. RITCHIE, MD, DAVID L. WILLIAMS, PhD, GEORGE HARP, PhD, JOHN L. STRATTON, MD, and JAMES H. CALDWELL, MD

Transaxial tomograhic imaging with thallium-201 was compared with standard, planar imaging in 38 patients with remote myocardial infarction and in 15 normal patients. Tomographic images were reconstructed from 64 views collected by a gamma camera that rotated about the anterior circumference of the patient's chest. A series of consecutive transverse-section images which encompassed the cardiac volume were reconstructed at a 6 mm plane spacing by filtered back-projection. No correction was made for attenuation losses. The set of transverse-section images was reformatted by 3-dimensional interpolation to obtain tomograms along the long and short axes of the myocardium. Tomographic and planar images were interpreted qualitatively.

Overall, tomography detected 33 of 38 (87%) prior infarctions whereas planar imaging detected 24 of 38 (63%) ($p = 0.01$). Improvement of the tomographic imaging method occurred only in the combined subset of transmural inferior and subendocardial infarctions, and not in transmural anterior infarctions. Peak increases in creatinine phosphokinase were smaller in patients detected only by tomography compared with those detected by both the planar and the tomographic approach (3.1 × normal versus 10.4 × normal, $p = 0.04$). Five patients (13%) with prior infarction were not detected by either approach. For 6 of the 9 patients detected by tomography alone, realignment of the image data along the short and long axes of the heart was essential for making the diagnosis. Fourteen of 15 patients without infarction were normal on both planar and tomographic imaging. A single normal patient had a defect detected by both techniques, yielding a specificity of 93% for each.

We conclude that transaxial tomography significantly improves the detection of thallium-201 myocardial perfusion defects in patients with prior myocardial infarction.

Thallium-201 is the current radionuclide of choice for the delineation of myocardial perfusion by gamma camera imaging. When injected after exercise or pharmacologic stress, regions of transient or reversible hypoperfusion may be identified in images taken immediately after isotope injection.[1-3] Imaging performed late after exercise-injection reflects a more basal distribution of blood flow; perfusion defects identified at this time usually define remote or prior myocardial infarction.[4,5] Similarly, defects identified by imaging performed at rest in stable patients demonstrate perfusion abnormalities that result from prior myocardial infarction.[6,7] The presence and extent of rest perfusion defects relate closely to quantitative indexes of prior myocardial infarction such as the extent and presence of regional contraction abnormalities.[6,7] In patients studied 6 to 12 months after acute myocardial infarction, the presence of a thallium-201 perfusion defect was more common than an identifiable wall motion abnormality or an electrocardiographic Q wave.[8] However, the planar imaging technique has inherent limitations. Considerable isotope is taken up by contiguous or nearby nonmyocardial structures such as lung and skeletal muscle. In planar imaging, this background or nonmyocardial activity to some extent overlaps myocardium in any given view and may mask the presence of perfusion abnormalities. Additionally, the truncated elliptical shape of the human heart dictates that some normal myocardium from an adjacent or opposing myocardial wall is partly superimposed on a given regional defect

and may similarly mask both the detection and the quantitation of perfusion deficits. Also, the low photon energy of thallium-201 results in considerable attenuation losses such that regions of the heart relatively deep in the body are underrepresented.

Transaxial tomography, an approach similar in theory to that of X-ray computed tomography, collects data circumferentially about 180 or 360° around the patient's chest; images are then reconstructed in discrete slices in the transaxial plane by computer techniques.[9–12] Reconstruction of these discrete transaxial slices should largely eliminate the problem of overlap of both adjacent normal myocardium and other noncardiac background structures. However, an accurate correction for attenuation losses in the thorax has yet to be accomplished for single photon studies (see later). In this study, we compared rest thallium-201 images obtained by the transaxial tomographic approach with standard planar images in the same patients with documented remote myocardial infarction. The purpose of this study was to ascertain whether qualitative analysis of transaxial tomographic images improves sensitivity or specificity in the detection of remote myocardial infarction compared with that of planar imaging.

Methods

Patient selection: Patients with prior myocardial infarction were selected from a clinic devoted to cardiovascular diseases by one of us as the first 38 patients agreeable to participate who fulfilled all of the following criteria: (1) either no or class I or II New York Heart Association stable angina pectoris; and (2) remote myocardial infarction identified by at least 2 of the 3 features: (a) electrocardiographic Q waves or S-T and T wave changes at the time of (b) an event characterized by prolonged and severe substernal chest pain and (c) elevation of creatinine phosphokinase to at least twice the normal value. These findings were ascertained by review of previous medical records by one of us.

These myocardial infarctions had occurred an average of 5.6 years before imaging (range 6 weeks to 12 years with all but 4 being 1 or more years). The peak creatinine phosphokinase level was known to be greater than twice normal in all but 2 of these patients. Because many of the events occurred in other hopsitals several years earlier, the magnitude of peak creatine kinase values were available in only 20 patients. Of the total of 38 patients with remote myocardial infarction, 16 had inferior, 11 had anterior, and 2 had combined anterior and inferior transmural myocardial infarction was evidenced by electrocardiographic Q waves of at least 0.03 second in duration in leads II, III, and aVF and/or the precordial leads, respectively. A single patient had isolated Q waves in leads I and aVL and was considered an anterior infarction. Three patients had inferior transmural myocardial infarctions with subsequent loss of diagnostic Q waves. These 3 patients were considered to have transmural infarction. Nine patients were designated as having had nontransmural infarction on the basis of S-T and T wave changes only without the development of new Q waves. In 4 of these cases ST-T wave changes were generalized; in 2 they were localized to the precordial leads and in 3 to the inferior leads. Fifteen patients without evidence of prior myocardial infarction were also studied. Eight of these patients were normal young volunteers under age 40 years who had no symptoms or signs of cardiovascular disease and who had normal electrocardiograms. Seven were patients who had undergone coronary angiography for suspected coronary disease but who had normal coronary arteries and normal left ventricular contraction patterns. All patients were advised of the experimental nature of the protocol and gave informed consent approved by the University of Washington Human Subjects Review Committee.

Image collection: One and a half microcuries of 201-thallous chloride was injected intravenously with the patient standing and after an overnight fast. Within 5 to 10 minutes, the patient was positioned on the imaging table and data collection started with a wide field of view camera (General Electric 400T, Milwaukee, Wisconsin) mounted on a rotating gantry positioned so that it could rotate freely about 360° around the patient's thorax. The camera head was adjusted to most closely approximate the left chest wall at the cardiac apex and yet clear the extreme right and left sides of the chest when rotated circumferentially about the body (Fig. 1 and 2). This positioning involved a fixed radius of rotation of 22 cm in diameter; the height of the table was adjusted for each patient to bring the camera head as close as possible to the chest wall at the apex of the heart.

The radius of rotation was monitored by a potentiometer mounted on one of the arms attaching the detector to the gantry. The voltage across the potentiometer was measured

by a 4-digit digital voltmeter. Variation of arm angle during data collection was better than 1 part in 300. Following the observation of Larsson,[13] who noted that virtually no cardiac thallium-201 activity was collected over the 180° farthest from the myocardium, we collected data only over the anterior myocardial 180° (Fig. 2). The long axis of the heart was assumed to approximate a 30° angle from the frontal plane, and image data were collected over 90° to either side of this angle (Fig. 2). A total of 64 discrete view images, that is, 1 image every 2.8°, were acquired over 180°. The image format was 128 by 128 and the counting rate was approximately 2,000 counts/s. With the high resolution, low energy collimator (round hole version), each image was acquired for 20 seconds for a total acquisition time of under 22 minutes. Immediately after tomographic collection, standard planar images were acquired on an Ohio Nuclear Series 100 scintillation camera equipped with an all purpose, low energy collimator. Anterior, 30° left anterior oblique, 45° left anterior oblique, and 60° left anterior oblique views of 300,000 counts each were obtained and displayed on tri-lens Polaroid film. In 9 patients, only 3 planar views were obtained because of prolonged set-up time early in the study. In each of these 9 cases, a defect was either present in multiple views or not present in any view, and the collection of an additional view would not have modified our interpretation (see later). Previous study in our laboratory has shown that in patients with stable, remote myocardial infarction injected at rest, images remain unchanged over a period of 1.5 to 2 hours[14]; that is, the presence of the defect is stable over the period of imaging. In 8 of the normal patients, the only images employed were those obtained at redistribution 2 to 3 hours after initial injection during treadmill exercise. Previous study in our laboratory showed that redistribution and rest images in normal patients were both normal and essentially identical.[5] The remaining 7 normal patients in this series had redistribution as well as separate rest images, which were visually identical.

Image processing: The projection images were low-pass filtered to reduce statistical noise by a 5 by 5 spatial convolving kernel with a frequency cutoff of 0.285 cycles per projection pixel. For each transverse section reconstructed, the corresponding 128-point projection arrays from each view were Fourier-domain filtered in a firmware array processor by a linear ramp that cut off sharply at the Nyquist frequency in reconstruction space (0.285 cycles per projection pixel). Each filtered projection was adjusted for center-of-rotation[15] and back-projected into a 64 by 64 image matrix. No noise smoothing was incorporated into the projection filtering. The set of transverse-sections reconstructed bracketed the cardiac volume in increments of 6 mm (every other axial projection pixel). These images were further processed to obtain tomograms in 3 orthogonal perspectives aligned with respect to the cardiac axes by the method developed in our laboratory by Olsen et al.[16] Thus, superior long axis, right anterior oblique long axis, and short axis cardiac tomograms were available for interpretation. This realignment provides no additional data, but simply displays them in an anatomically oriented format in which abnormalities of perfusion are more easily assimilated.

We did not employ computer processing in the analysis of the planar images, as an earlier study from our laboratory had shown no significant improvement over analysis of the tri-lens Polaroid format.[14]

Image interpretation: All images were interpreted qualitatively by 2 observers unaware of clinical information. A perfusion defect was defined as a discrete regional count deficit visually estimated at ≥50% that of adjacent walls and encompassing ≥20% of the circumference of the myocardium, present in at least 2 views on the planar studies and at least 2 slices on the tomographic studies, as previously defined in our laboratory in several series.[2,5,7,14] In 4 cases there was observer disagreement and a consensus was employed.

TABLE I Thallium-201 Transaxial Tomography: Type and Location of Myocardial Infarction (n = 38)

	Tomography Only (n = 9)	Planar and Tomographic Imaging (n = 24)	Not Detected (n = 5)
AMI	1	12	...
DMI	4	11	1
SEMI	4	1	4

AMI = anterior myocardial infarction; DMI = diaphragmatic or inferior myocardial infarction; SEMI = subendocardial myocardial infarction.

Results

Among the 38 patients with prior myocardial infarction, 24 (63%) had perfusion abnormalities on both transaxial tomographic and planar imaging. In 9 patients (24%), perfusion defects were identified by tomography but not by planar imaging. In 5 patients (13%), tomographic as well as planar images were entirely normal (Table I, Fig. 3). In no patient was a defect seen on planar images and not on tomographic study. Overall sensitivity in the detection of prior myocardial infarction by the tomographic technique was 33 of 38 (87%) and by the planar technique 24 of 38 (63%). The detection of defects by the tomographic approach was statistically significantly greater at the $p = 0.01$ level (McNemar test of correlated proportions). In the 15 patients without myocardial infarction, all but 1 patient was correctly identified as normal by each technique. That patient had an inferior defect on both tomography and the planar approach and had typical exertional angina and normal coronary arteries. Specificity was thus 93% for both the tomographic and the planar approaches.

The type of infarction (transmural or subendocardial) and location are shown in Table I. Four of the 5 patients with prior infarction not detected by either imaging modality had subendocardial infarction; the fifth had

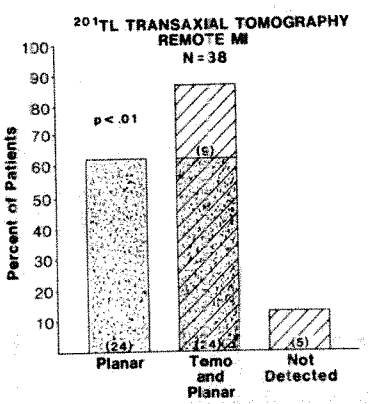

FIGURE 3. Of patients with prior infarction 63% were detected by planar imaging (**left**), 87% by tomography (Tomo) (**center**), and 13% were not detected by either approach (**right**). MI = myocardial infarction.

an inferior transmural infarction. Four of the 9 patients (44%) whose infarction was detectable only by tomography had subendocardial infarctions. The remaining 5 patients detected only by tomography had transmural infarction and 4 of these 5 were inferior. Of the 24 patients with infarctions detectable by both planar and tomographic imaging, only 1 (4%) had a subendocardial infarction. When patients with inferior and subendocardial infarctions were considered together, significantly more infarctions were detected by the tomographic (20 of 25, 80%) than the planar approach in this subset (12 of 25, 48%; $p = 0.01$, McNemar test). This was not the case for anterior transmural infarctions as only 1 of 13 such patients had detection by tomography alone. The distribution of patients with subendocardial myocardial infarctions localized electrocardiographically did not differ in the 3 groups, although the number of cases was small.

In those patients identified only by tomography, peak creatinine kinase was 3.1 ± 1.5 (standard deviation) times normal ($n = 6$) versus 10.4 ± 7.8 times normal ($n = 11$) in patients identified by both tomography and planar imaging ($p = 0.04$, Student's t test). The mean time between infarction and imaging, however, did not differ in these 2 groups (5.2 ± 2.8 years tomography alone versus 4.5 ± 4.0 years tomography and planar detection, p = not significant). All 3 patients in whom electrocardiographic Q waves disappeared over time were in the group detected by both planar and tomographic approaches. This number was too small for statistical analysis.

Additionally, in the 9 patients with perfusion defects seen only on tomography, 6 (67%) were identified only in the images realigned along the principal long and short cardiac axes. The sensitivity for detection of infarction by transverse or transaxial tomograms was 27 of 38 (71%) compared with 33 of 38 (87%) for the realigned tomograms. This figure represented a statistically significant difference at the $p = 0.05$ level. Thus, most of the improvement in sensitivity with the tomographic approach required realignment along the principal myocardial axes.

Figure 4 illustrates a patient with a prior transmural diaphragmatic myocardial infarction in whom the planar images were normal. The tomographic study, however, showed a definite inferior perfusion defect, seen best on the short axis and right anterior oblique long axis perspectives and not clearly defined in the reconstructed transaxial images. Figure 5 illustrates a patient with an inferior, transmural myocardial infarction. Although the planar images were interpreted as showing a perfusion defect, it was poorly defined (Fig. 5A). The defect is not seen in the transaxial tomographic slices (Fig. 5B). The short axis tomographic image, however, clearly identifies an inferior abnormality present in 3 discrete slices (Fig. 5C).

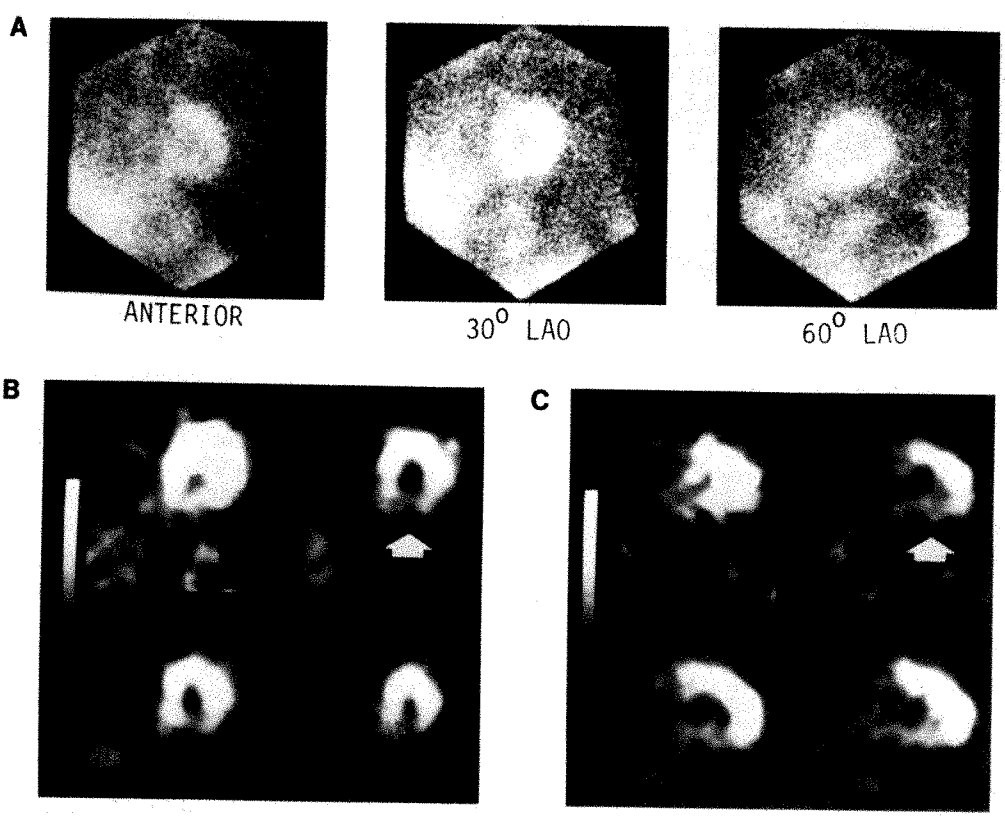

FIGURE 4. Patient with prior transmural inferior myocardial infarction. **A**, the planar images are normal. **B**, short-axis tomographic slices begin at the base (**upper left**) and work toward the apex (**upper right, lower left, lower right**); a defect is seen in 1 slice shown by the **arrow**. **C**, right anterior oblique slices (perpendicular to the short axis beginning with the right ventricle and septum and slicing toward the lateral wall). The inferior defect is shown by the **arrow**.

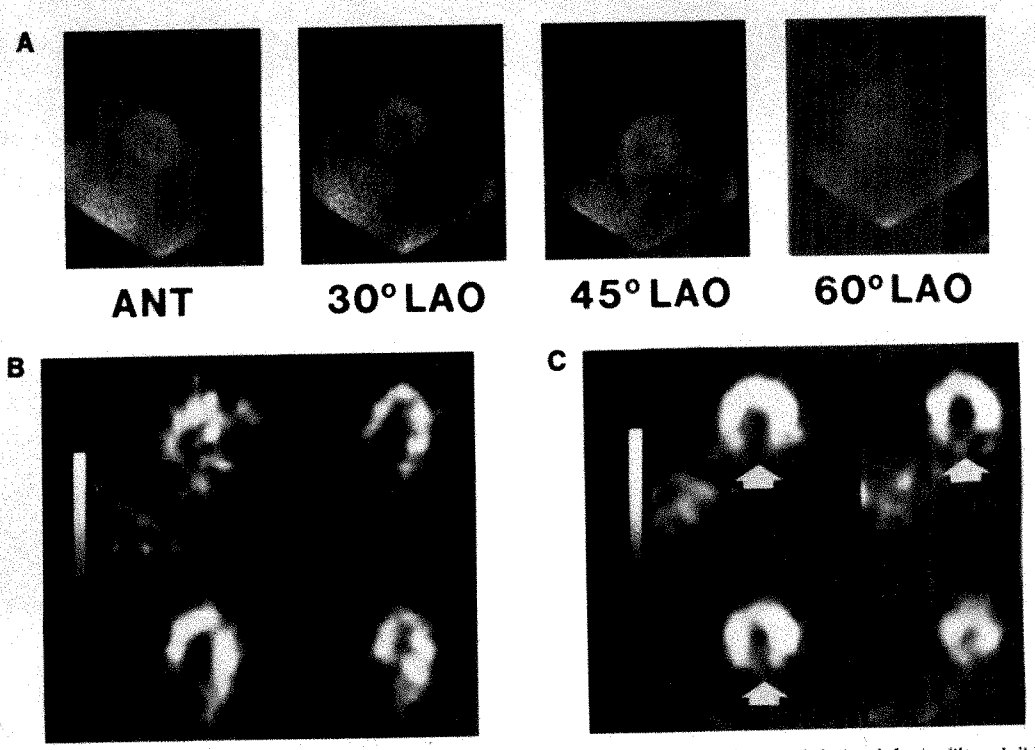

FIGURE 5. Patient with a transmural inferior myocardial infarction. **A**, planar images were read to show an inferior defect, although it is poorly visualized. (Reproduced with permission from Olson et al.[16]) **B**, transaxial slices beginning toward the feet (**upper left**) and working upward (**upper right, lower left, lower right**) do not clearly show an abnormality. **C**, short-axis views show a clear, well-demonstrated inferior defect in 3 slices (**arrows**).

In all cases, the anatomic location of perfusion defects was concordant when present in both planar and tomographic studies and corresponded with the electrocardiographic location of Q waves. In 3 of the tomographic studies, however, defect size appeared visually more extensive than that seen on the planar study.

Discussion

In this study of a gamma camera-based transaxial tomographic system, we assessed stable patients with remote myocardial infarction. In an earlier evaluation of the 7-pinhole approach to emission tomography, we showed that repeat tomograms obtained over a 1.5 to 2 hour period were stable and identical.[14] Thus, in the current study we compared a single transaxial tomographic study with standard planar scintigraphy performed at rest. The 7-pinhole or limited-angle approach to tomography did not yield improved sensitivity or specificity in the detection of remote myocardial infarction when studied in 48 patients (a series similar in size to the prsesent study) in our laboratory.[14] In contrast, transaxial tomography appears to offer improved sensitivity in the detection of perfusion defects in this preliminary series. The collection of data for 180° about the object fulfills the mathematic requirements for tomography as initially proposed by Radon[17] in 1917; that is, the object is viewed or imaged from all sides or perspectives, as distinguished from the 7-pinhole approach in which data are sampled over a maximal angle of about 85°. Of particular importance in the present approach was the realignment of the reconstructed transaxial images along the 3 orthogonal long and short axes of the heart. Perfusion defects often involve the inferoapical cardiac surface, which may fall entirely within a single transaxial slice and thus be hard to define; that is, a slice through the defect may show no myocardial activity, whereas the adjacent slice may then appear relatively uniform, without a definite perfusion defect, as shown in the transaxial slices in Figure 5B. Reorientation of the slice axes to coincide with the myocardial long and short axes best allows direct comparison of 1 wall to the opposite wall, and in the 2 long axis views, allows ready appreciation of apical abnormalities. Commonly, the short axis display most clearly separates perfusion defects into the coronary arteriographic beds as shown by the example in Figure 5C in which a defect involving the distribution of the posterior descending coronary artery (the inferior portion of the septum) is clearly shown.

As anticipated, myocardial infarctions detected by tomography alone appeared to be smaller than those detectable by both the tomographic and the planar approaches as evidenced by lower peak creatinine kinase values and the predominance of inferior and subendocardial infarctions. Studies by Niess et al[6] as well as our own earlier report[7] have shown a sensitivity of greater than 90% in the detection of infarction associated with electrocardiographic Q waves. The identification of 63% of all infarctions in this series is similar to the 75% sensitivity of Niess et al[6] for combined transmural and nontransmural infarctions and is similar to our earlier report identifying 69% of remote infarctions in a series of transmural and nontransmural in-

farctions.[14] Tiefenbrunn et al[8] reported a higher sensitivity; it seems likely that patient selection factors explain these differences and that our ambulatory population included more patients with smaller infarctions than some other series. Mueller et al,[18] in a related experimental model of canine myocardial infarction, found that ischemic zones of less than 5 g were not identified by planar imaging.

Single-photon transaxial tomography has been performed in both experimental and clinical settings for over a decade, initially by Kuhl and Sanders,[9] who demonstrated improved detectability of cerebral mass lesions. Similarly, Keyes,[10] Burdine,[11] Budinger,[12] Holman,[19] and their co-workers have reported feasibility and early clinical experiences. These early investigators used either uniquely designed systems or non–gamma camera-based systems. The current study employed a commercially available, gantry-suspended rotating gamma camera. This system and others like it are now becoming generally available at a cost only moderately higher than that of the gamma camera alone. Because the gamma camera may also be used for standard imaging, wide clinical use is feasible. The reconstruction software used for our study was implemented locally on a standard nuclear medicine computer system (Medical Data Systems A^2 computer, Ann Arbor, Michigan). Other reconstruction algorithms for this gamma camera system are available; that developed by Larsson[13] was recently described in detail.

We employed no attenuation correction in these studies but followed the observation of Larsson[13] and collected view data only over the 180° angular interval most anterior to the myocardium. Image quality was satisfactory, probably reflecting the relative centering of the heart with respect to soft tissue and body attenuation in the thoracic wall (Fig. 2). Without an attenuation correction, absolute quantitation of regional myocardial perfusion is not possible. To date, no satisfactory approach to this problem for the thorax has been implemented. Attenuation losses in the 180° of view data most distant from the heart are considerable. These data add little other than noise to reconstruction, and when combined with the anterior view data, reconstruction quality is degraded (unpublished observation).

In conclusion, this preliminary clinical study of patients with prior myocardial infarction supports the thesis that single-photon transaxial tomography improves the detection of perfusion defects with thallium-201. The collection of data for only the anterior 180° about the heart as well as reorientation of the tomographic images along the long and short axes of the myocardium were important contributing features to this improvement. It is not known whether the relatively long data collection time of 22 minutes will allow the application of this approach to transient perfusion abnormalities induced by exercise, but this subject deserves study.

Noninvasive Detection of Multivessel Disease After Myocardial Infarction by Exercise Radionuclide Ventriculography

ALAN G. WASSERMAN, MD, RICHARD J. KATZ, MD, PATRICIA CLEARY, MS, VIJAY M. VARMA, MD, RICHARD C. REBA, MD, and ALLAN M. ROSS, MD

The ability of exercise radionuclide ventriculography to detect multivessel coronary artery disease in patients who survived a single myocardial infarction was assessed. Seventy-four patients who had had myocardial infarction at least 8 weeks earlier underwent cardiac catheterization and exercise radionuclide ventriculography. Thirty-eight patients had had an inferior infarction: 25 with multivessel disease and 13 with single vessel disease of the right coronary artery. Thirty-six patients had had an anterior infarction: 26 with multivessel disease and 10 with single vessel disease of the left anterior descending coronary artery.

Among patients with anterior infarction there was no significant difference between patients with single vessel disease and patients with multivessel disease with regard to resting ejection fraction, exercise ejection fraction, and the mean change from rest to exercise. Patients with single vessel disease had a decrease in ejection fraction from rest to exercise of 2.2 ± 2.7% units (mean ± standard error [SE]), compared with a decrease of 5.4 ± 1.3% units in those with multivessel disease (p = not significant [NS]). Seventeen of 26 (65%) patients with multivessel disease and 6 of 10 (60%) with single vessel disease had a decrease in ejection fraction of at least 5 percentage units (p = NS).

In patients with inferior infarction there was no difference in the mean resting ejection fraction in those with single vessel disease (53 ± 2%) compared with those with multivessel disease (50 ± 2%); however, the mean exercise ejection fraction in patients with single vessel disease (57 ± 3%) was significantly higher (p <0.005) than that in patients with multivessel disease (45 ± 2%). Sixteen of the 25 patients with multivessel disease (64%) but only 1 patient with single vessel disease (7.7%) had a decrease in ejection fraction of at least 5 percentage units (p <0.001).

A new wall motion abnormality developed in 8 patients with anterior infarction and 11 with inferior infarction with multivessel disease and none with single vessel disease. The sensitivity and specificity in predicting multivessel disease using the criteria of the development of a new wall motion abnormality or a decrease in ejection fraction with exercise of at least 5 percentage units were 80 and 92% for the patients with inferior infarction, but only 69 and 40% for the patients with anterior infarction.

These results suggest that exercise radionuclide angiography can be used to discriminate between single and multivessel disease after inferior myocardial infarction. For patients with anterior infarction, only a new abnormality in wall motion accurately predicts multivessel disease, but this occurred in only one third of such patients.

The long-term prognosis of patients who survive myocardial infarction depends on the extent of coronary artery narrowing and the degree of left ventricular dysfunction.[1-3] The application of coronary artery bypass to improve prognosis in selected patients with multivessel disease has stimulated interest in identifying them from within the overall group of survivors of infarction.

Exercise radionuclide ventriculography has been shown to be a reliable noninvasive tool for diagnosing significant coronary artery disease.[4,5] However, its role in predicting the extent of disease in patients who have had a myocardial infarction remains unclear. In this study we evaluated the ability of exercise radionuclide ventriculography to detect multivessel disease after myocardial infarction.

Methods

Study population: The study group consisted of 74 consecutive patients, 70 men and 4 women, with a mean age of 52 years (range 30 to 71) referred for coronary arteriography for various reasons including chest pain, evaluation of the extent of coronary artery disease, age, and arrhythmias. All patients had had a single myocardial infarction at least 2 months before the study. Myocardial infarction was documented by history, hospital records, and residual, significant (≥0.04 mm) Q waves on the resting electrocardiogram. Thirty-eight patients had had inferior infarctions and 36 anterior infarctions. Testing was performed within 6 months after infarction in 29, at 6 months to 1 year in 15, and after 1 year in 30. The mean time after infarction was 17 months in patients with inferior and 22 months in those with anterior myocardial infarction. Exercise radionuclide ventriculography was performed within 1 week of coronary arteriography in all patients.

Coronary arteriography: Selected coronary arteriography was performed using the percutaneous femoral technique in all patients. Studies were independently reviewed by 2 experienced angiographers without knowledge of the radionuclide results. Coronary stenosis was considered significant when luminal diameter was narrowed ≥70% (except in the left main coronary artery, where 50% narrowing was considered significant). Patients with disease of the left main coronary artery were classified as having multivessel disease.

Rest and exercise imaging procedure: In vivo labelling of red blood cells with 25 to 30 mCi of technetium-99m pertechnetate was accomplished by injecting this radiopharmaceutical 20 minutes after intravenous administration of 7.5 mg of stannous pyrophosphate. Gated radionuclide ventriculograms were obtained using a portable scintillation camera (Ohio Nuclear Series 420) with an all-purpose parallel hole collimator interfaced to a Medical Data Systems computer (A^2). The camera was positioned to obtain the left anterior oblique view that maximized separation of ventricular images. Gated images were acquired over 2 minute intervals, at 20 frames per cardiac cycle, at rest, and during the last 2 minutes of each 3 minute stage of graded supine bicycle exercise. Only the study acquired at peak exercise was used for analysis.

The left ventricular time activity curve was generated using a conventional software program (Medical Data Systems) containing semiautomatic edge detection and computer-determined background algorithms. Left ventricular ejection fraction was automatically calculated directly from the time activity curve. This method correlates well with results obtained in our Cardiac Catheterization Laboratory when compared with single plane contrast ventriculography in 50 consecutive patients ($r = 0.89$) (unpublished results).

Wall motion was evaluated by viewing the cardiac cycle in a loop movie format by 2 independent experienced observers without knowledge of cardiac catheterization data. The rest and peak exercise studies were viewed side by side to detect the development of an exercise-induced wall motion abnormality in 1 of 3 anatomic sites: septal, inferoapical, and posterolateral (Fig. 1). Because all of our patients had septal and inferoapical resting wall motion abnormalities after anterior myocardial infarction, a new abnormality was considered only when it occurred in the posterolateral wall; likewise, a new abnormality was considered only when it occurred in the septal region in patients after inferior myocardial infarction. Wall motion for each region was graded as follows: 3 = normal, 2 = mild hypokinesia, 1 = moderate to severe hypokinesia, 0 = akinesia, and −1 = dyskinesia. A change in score of at least 2 grades was considered to represent an exercise-induced abnormality. Agreement was exact in 81% (180 of 222) of regions. Differences in the remainder of the regions were resolved by joint review and arbitration of the studies by a third observer.

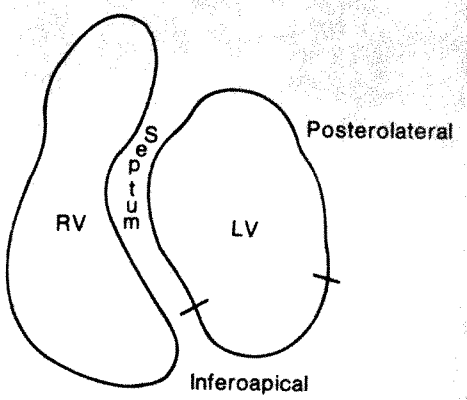

FIGURE 1. Schematic division of the left ventricle (LV) into septal, inferoapical, and posterolateral regions. RV = right ventricle.

Exercise protocol: Maximal graded supine bicycle exercise was performed starting at a work load of 200 kg-m/min and was increased by 200 kg-m/min increments every 3 minutes. Exercise was continued until the development of angina pectoris, dyspnea, or fatigue. Electrocardiographic recordings were obtained continually (lead II) during exercise and for 5 minutes after exercise. Administration of long-acting nitrates was stopped at least 8 hours before this study, but that of beta-blocking drugs was continued.

Analysis of data: All statistical analyses were performed with the Statistical Analysis System. For qualitative variables (such as sex) which are expressed as percentages, the chi-square test of association in contingency tables was used to test for differences between the groups. The quantitative data are presented as means ± standard error of the means. For quantitative variables, a least-squares analysis of variance was employed to compare the means. Covariance analysis was used to adjust means for differences between the groups on the basis of following variables: age, time since myocardial infarction, and use of beta-blocking drugs. For the principal outcomes of this study, a probability level of $p < 0.05$ was considered significant.

Results

Coronary angiography: Among patients with anterior myocardial infarction, 26 had multivessel disease which was distributed as follows: left main artery stenosis, 5 patients; triple vessel disease, 16 patients; double vessel disease with left anterior descending and right coronary artery involvement, 5 patients. The remaining 10 patients had single vessel left anterior descending artery disease. All patients had segmental wall abnormalities on contrast ventriculography consistent with prior anterior or anteroseptal myocardial infarction.

Among patients with inferior myocardial infarction, 25 had multivessel disease: left main stenosis in 9 patients, triple vessel disease in 12, and double vessel disease with left anterior descending and right coronary involvement in 4. Thirteen patients had disease isolated to the right coronary artery. All patients had inferior

wall motion abnormalities on contrast ventriculography.

Exercise radionuclide ventriculography: anterior myocardial infarction: Among the patients who had anterior myocardial infarction there was no significant difference between those with multivessel and those with single vessel disease with regard to the percentage receiving beta-blocking agents, the peak exercise heart rate or double product, or the percentage of patients in whom exercise-induced angina developed (Table I). On the average, those with single vessel disease were able to exercise longer (8.9 ± 1.3 minutes versus 6.0 ± 0.5 minutes) ($p < 0.03$), but there was considerable overlap between groups.

The mean resting ejection fraction was similar in the 2 groups (multivessel 40 ± 2%, single vessel 45 ± 3%). All patients demonstrated wall motion abnormalities in both the septal and inferoapical regions. The mean peak exercise ejection fraction in the patients with multivessel disease was somewhat lower (34 ± 2%) than that in those with single vessel disease (43 ± 3%) (Fig. 2), but this difference did not achieve statistical significance ($p < 0.10$). The magnitude and direction of the ejection fraction response to exercise, however, did not

				p <0.01
Δ EF	−2.2 ± 2.7	−5.4 ± 1.3	+3.8 ± 2.5	−5.2 ± 1.4
				p <0.001
% ↓5 units	60.0	65.4	7.7	64.0
		p <0.05		p <0.005
% developing new WMA	0.0	30.8	0.0	44.0

Values expressed as mean ± standard error of the mean. ΔEF = mean ejection fraction change from rest to exercise; MI = myocardial infarction; MVD = multivessel disease; % ↓5 units = percentage of patients with a decrease in ejection fraction of at least 5 percentage units; SVD = single vessel disease; WMA = wall motion abnormality.

distinguish the patients with single vessel disease from those with multivessel disease. The mean change in ejection fraction in response to exercise was −5.4 ± 1.3 units in patients with multivessel disease and −2.2 ± 2.7 units in those with single vessel disease (p = NS). Of particular interest is that even a marked exercise-induced decrease in ejection fraction of ≥5 units did not separate multivessel disease patients from those with single vessel disease. Seventeen of 26 (65%) patients with multivessel disease and 6 of 10 (60%) with single vessel disease had a decrease in ejection fraction from rest to exercise of ≥5 percentage units. Thus, in this important variable there was no difference between patients with single and multivessel disease (Table II).

A new wall motion abnormality developed in 8 of 26 (30.8%) patients with multivessel disease, but none in patients with single vessel disease (Table II). Combined analysis of the exercise ejection fraction response and wall motion changes in patients with multivessel disease revealed a new wall motion abnormality alone in 1 patient, an ejection fraction decrease of ≥5 units without a wall motion change in 10 patients, and both a new wall motion abnormality and a marked ejection fraction decrease in 7 patients. Thus, using both ejection fraction and wall motion analysis criteria, radionuclide testing correctly predicted multivessel disease in 18 of 26 patients (69%) while incorrectly predicting single vessel disease in 6 of 10 patients (sensitivity 69%, specificity 40%).

Inferior myocardial infarction: There were no significant differences between patients with multivessel and those with single vessel disease with regard to the percentage taking beta-blocking drugs, peak exercise heart rate, double product, or the percentage in whom exercise-induced chest pain developed. Patients with single vessel disease were able to exercise slightly longer than those with multivessel disease (8.7 ± 0.9 versus 6.8 ± 0.5 minute) (p <0.10) (Table I).

The mean resting ejection fractions were similar in both groups (multivessel 50 ± 2%, single vessel 53 ± 2%). All patients demonstrated inferoapical wall motion dysfunction. In contrast to those patients with anterior myocardial infarction, the ejection fraction response to exercise in patients with single vessel disease differed significantly from that in patients with multivessel disease (Fig. 2). The mean exercise ejection fraction increased from 53 ± 2% to 57 ± 3% in patients with single vessel disease whereas it decreased from 50 ± 2% to 45 ± 2% in patients with multivessel disease. The mean change in ejection fraction was significantly different in the 2 groups, patients with single vessel disease having an absolute increase of 3.8 ± 2.5 units compared with a decrease of 5.2 ± 1.4 in patients with multivessel disease (p <0.01). Sixteen of the 25 patients with multivessel disease (64%) but only 1 patient with single vessel disease (7.7%) had a decrease in ejection fraction with exercise of ≥5 percentage units (p <0.01) (Table II). Therefore, the sensitivity and specificity for predicting multivessel disease were 64% and 92.3% for a decrease in ejection fraction of ≥5%.

Table II demonstrates further that during exercise in 11 patients (44%) with multivessel disease a new septal wall motion abnormality developed indicative of disease in the left anterior descending artery. No new wall motion abnormalities were seen in those with only single vessel disease. Combined analysis of the exercise ejection fraction response and wall motion changes in patients with multivessel disease revealed a new wall motion abnormality alone in 4 patients, an ejection fraction decrease of ≥5 units without a wall motion change in 9 patients, and both a new wall motion abnormality and a marked ejection fraction decrease in 7 patients. Thus, using both criteria, radionuclide testing correctly predicted multivessel disease in 20 of 25 patients (80%) while only incorrectly predicting it in 1 patient. Combined criteria for predicting multivessel disease increased the sensitivity to 80% without changing the specificity from 92.3%.

Discussion

In recent years noninvasive techniques have been used after myocardial infarction to determine the presence of multivessel coronary artery disease and thus assess prognosis. Previous studies applied submaximal and maximal treadmill exercise testing, thallium per-

'usion imaging, and, to a limited extent, radionuclide ventriculography. In this study radionuclide ventriculography was evaluated as a prognostic method.

Our data show that with documented anterior myocardial infarction, neither the resting ejection fraction nor the ejection fraction response to exercise can be used to predict additional coronary disease beyond the distribution of the left anterior descending artery. The development of a new exercise-induced posterolateral wall motion abnormality is a specific (8 of 8, 100%), albeit insensitive (8 of 26, 31%), means of detecting multivessel disease in these patients.

For patients with previous inferior myocardial infarction however, the results differ and are more clinically useful. Both exercise ejection fraction response and wall motion analysis can discriminate single from multivessel disease. A combination of these criteria correctly predicted multivessel disease in 20 of 25 patients (80%) while incorrectly predicting it in only 1 patient with single vessel disease.

When further analysis was performed using least-square means adjusted for age, time from myocardial infarction, and use of beta-blocking drugs there was no significant change in any of the aforementioned results. Although this series was consecutive and unselected in terms of exercise radionuclide testing, the patients were entered into the study on the basis of referral for angiography. This population thus represents postinfarction patients commonly referred for cardiac catheterization and may not represent all postinfarction patients. The majority of patients in both infarct groups did not have exercise-induced angina (Table I). Inferior myocardial infarction group analysis of only the subset without angina continued to discriminate patients with multivessel disease from those with single vessel disease.

Further analysis was also performed among patients with multivessel disease after both anterior and inferior myocardial infarction. Comparisons between patients with left main, triple, and double vessel disease revealed no significant difference in exercise duration, ejection fraction, or wall motion among these 3 subgroups. Thus, we were not able to discriminate patients with left main vessel disease from those with double or triple vessel disease. The results of our study add to previously reported data on risk group stratification after myocardial infarction.

Submaximal exercise combined with radionuclide ventriculography before hospital discharge after acute myocardial infarction was recently found by Corbett et al[6] to be a sensitive means of identifying patients at high risk for a subsequent cardiac event within 6 months. Similar to results of a previous study by Pulido et al[7] but unlike those of Borer et al,[8] Corbett et al found that exercise ejection fractions varied significantly with exercise and these changes correlated with early postmyocardial infarction cardiac events. In Borer's study however, no significant change was seen between resting and exercise ejection fraction early after myocardial infarction, although a subgroup of patients with a resting ejection fraction >40%, did have a small but significant increase in ejection fraction when studied 6 to 14 months after myocardial infarction. Our patients are not comparable to the ones in these studies in that all patients had had myocardial infarction at least 8 weeks earlier. These studies do stress the problem of defining a "normal" ejection fraction response after myocardial infarction. Obviously factors such as the extent of infarction, time since infarction, and presence of additional coronary disease will determine the response to exercise in addition to other variables present in patients without infarction such as age, sex, and duration of exercise. We did not attempt to define a "normal" response but investigated whether differences in the magnitude of the exercise ejection fraction response could separate patient groups.

Our strict criteria for a new wall motion abnormality accounts for its high specificity and low sensitivity in detecting multivessel disease in both groups with myocardial infarction. This approach seems appropriate, however, in that in a patient with a prior anterior myocardial infarction, deterioration of the inferoapical segment may be secondary either to left anterior descending artery disease or to additional right coronary artery disease. Likewise, after inferior myocardial infarction, deterioration of the posterolateral segment may be secondary to disease in either the right or circumflex coronary artery. DePuey et al[9] reported results similar to ours regarding the specificity and insensitivity of wall motion abnormalities.

Shah et al,[10] in reporting their experience with wall motion on resting radionuclide ventriculograms performed during the acute setting in patients with inferior myocardial infarction, found a significantly increased incidence of wall motion abnormalities in areas remote from the infarction in a subgroup of patients with poor short-term morbidity and mortality. Although coronary arteriography was not performed, these changes were assumed to be secondary to concomitant disease in the left anterior descending artery.

Even with the self-imposed limits placed on our wall motion analysis, we believe that a new wall motion abnormality remains an important and reliable finding. Perhaps repeated exercise studies with an anterior view in patients with inferior myocardial infarction to evaluate the anterior wall, and a left lateral view in patients with anterior myocardial infarction to evaluate the inferior wall, would lead to improved sensitivity.

Postinfarction testing with thallium-201: Studies indicate that thallium-201 myocardial perfusion scanning with and without exercise stress testing is also a reliable detector of patients with multivessel disease after myocardial infarction.[11-14] However, in a study population similar to ours Rigo et al[15] examined 101 patients a minimum of 3 months after myocardial infarction using thallium-201 imaging and maximal exercise stress testing. As with our experience they were only able to detect multivessel disease in 1 of 12 patients with a prior anterior infarction, but were able to detect left anterior descending artery disease with a sensitivity of 69% in patients after inferior myocardial infarction.

Postinfarction testing using the exercise treadmill test: In patients after myocardial infarction early submaximal and late maximal treadmill stress testing

has been used to assess the presence of multivessel disease.[16–20] Castellanet et al[18] reported that after inferior myocardial infarction the S-T segment response had excellent sensitivity (87%) and specificity (90%) in detecting additional disease. Similar to our results, they found that after anterior infarction there was a reduced sensitivity (52%) with retained specificity (90%) for detecting additional disease. Paine et al[19] also showed that S-T segment changes are less sensitive in diagnosing additional coronary disease after anterior rather than after inferior myocardial infarction. In a study of 52 patients after inferior wall myocardial infarction, Miller et al[20] reported a positive exercise test result in 32 of 41 patients (78%) with multivessel disease, but also in 5 of 11 (46%) with single vessel disease.

Conclusions: Considering our data and previous reports on prognosis stratification it now seems reasonable to conclude that after inferior wall myocardial infarction, the low and high risk subgroups (or patients with single versus those with multivessel disease) can be accurately identified by exercise radionuclide ventriculography and by other analogous noninvasive tests.

In contrast, for late survivors of anterior infarction, neither exercise radionuclide ventriculography nor other noninvasive investigations differentiate patients with single or multivessel disease with sensitivity or specificity sufficient to be clinically reliable. For purposes of prognostication and intervention, coronary angiography remains the only presently reliable method to assess the extent of coronary artery disease in this patient population.

Importance of Coronary Risk Factors in the Presence or Absence of Myocardial Ischemia

MARKKU HELIÖVAARA, MD, MARTTI J. KARVONEN, MD, PhD, SVEN PUNSAR, MD, and JAASON HAAPAKOSKI, MSC

Smoking history, systolic blood pressure, and serum cholesterol concentration were studied for their value in predicting 5-year coronary mortality in middle-aged and older Finnish men. Total experience consisted of 188 deaths from ischemic heart disease during 20,245 person-years. Initially, the men were divided into 3 groups according to the degree of myocardial ischemia: (1) previous myocardial infarction; (2) ischemic heart disease without infarction; and (3) no myocardial ischemia.

The 3 main risk factors were associated, independently of each other and of age, with the relative risk of coronary death similarly in the 3 groups, whereas their absolute impact on mortality was strong among men with ischemic heart disease and even stronger among those with a prior myocardial infarction. For example, the estimated excess coronary mortality attributable to smoking 10 to 19 cigarettes per day was 6.3 deaths per 1,000 person-years in the group with no ischemia, 14.6 in the ischemia group, and 43.1 in the infarction group.

The results suggest that secondary prevention of ischemic heart disease may be important. Screening of coronary disease among middle-aged and older men also appears justified.

Cigarette smoking, elevated blood pressure, and high concentration of serum cholesterol increase the risk of a healthy person dying from ischemic heart disease. Yet, the significance of these risk factors in persons who already have clinically manifest myocardial ischemia is still unclear.

Epidemiologic data on the predictive power of risk factors at various stages of coronary atherosclerosis and in different clinical manifestations of ischemic heart disease help clarify the etiology and pathogenesis of coronary disease. Such basic data are also needed to evaluate the potential usefulness of secondary prevention of the disease.

The aim of the present study was to compare the effects of major risk factors on coronary mortality in 3 subgroups of men: those who in screening examinations showed evidence of a prior myocardial infarction, ischemic heart disease without infarction, or no myocardial ischemia. In addition to the relative risks, the risk attributable to each factor was also considered in order to evaluate the potential benefit of preventive measures.

Methods

Patient population: In 1959, there were 1,711 men aged 40 to 59 years from rural areas of eastern and southwestern Finland who were enrolled in a prospective study of coronary heart disease and other cardiovascular diseases.[1,2] The cohorts were followed up for deaths until 1974. The survivors were reexamined at 5-year intervals, in 1964, 1969, and 1974. The participation rate at each examination was about 95 to 98%.

Examinations: The methods used to obtain clinical and other data as well as data on resting and postexercise electrocardiogram, blood pressure, serum cholesterol concentration, and smoking habits have been described elsewhere.[1,2] All clinical data were evaluated centrally and classified according to set rules. The identification of coronary deaths was based on careful analysis of the circumstances of death.[2]

Identification of ischemic heart disease and prior myocardial infarction: The data obtained on cardiac status and the risk factors at each field examination were used to predict coronary deaths during the subsequent 5 years, independently of the data from previous or later field examinations. Therefore, the following hierarchical system was used to classify the men according to the degree of myocardial ischemia: (1) previous myocardial infarction; (2) ischemic heart disease without infarction; and (3) no myocardial ischemia. A subject was classified as having had myocardial infarction when there was a history of a verified infarction or when the resting electrocardiogram showed major Minnesota code Q or QS abnormalities (original Minnesota code[3] items 1:1, or 1:2 and 5:1,2). In the absence of infarction, a subject was classified as having myocardial ischemia when there was a history of definite or probable angina on effort[4]; when the resting electrocardiogram showed lesser Q or QS changes (items 1:2,3) or abnormalities of T-wave, atrioventricular, or

ventricular conduction (5:1–3; 6:1,2,4; 7:1,2,4), or atrial fibrillation; or when there was a horizontal or downward sloping S-T segment depression of at least 0.5 mm.[4] The majority of men (over 96% in 1959 and 1964, 89% in 1969) who did not have the foregoing symptoms or electrocardiographic signs performed an exercise test. In the group with myocardial ischemia were included those men who only had S-T segment depression in the 1-minute postexercise record.

To improve the diagnostic accuracy of the categories, subjects were excluded from the study when there were indications of pulmonary, rheumatic, or syphilitic heart disease, except when associated with major Q or QS changes. The number of excluded men varied from 13 to 32 between examinations.

Statistical analysis: The data of the 3 field examinations and of the three 5-year periods were pooled. The pooled person-years thus consist of the experience of 3 follow-up periods and refer to the length of observation from the time of the initial examination until reexamination or death, whatever the cause.

Because our aim was to demonstrate the independent predictive significance of each major risk factor, the possible confounding effects of age, geographic location, and risk factors other than the explanator had to be considered. A multifactorial analysis was therefore performed. A log-linear model[5] was formulated as follows: $\log T = \beta_\theta + \beta_1 x_1 + \ldots + \beta_k x_k + W$, where T equals the time span from entry to coronary death; $x_1, \ldots, x_k$ are the values of explanatory and confounding variables; $\beta_1, \ldots, \beta_k$ equals the values of coefficients; and W is an error variable corresponding to the exponentially distributed T. The model assumes that the intensity of coronary mortality remains constant for each 5-year period of follow-up study and that log T is a linear function of explanatory and confounding variables. Age (in years), blood pressure (in millimeters of mercury), and serum cholesterol concentration (in milligrams per 100 milliliters) were used as continua. Because systolic and diastolic pressures have closely predicted survival in a similar way in this series,[2] only the systolic pressure was included in the analysis. The following separate categories were used to evaluate the history of smoking: never smoked (control); stopped smoking; pipe or cigar smoker; cigarette smoker consuming either 1 to 9, 10 to 19, or 20 or more cigarettes per day.

Analyses were made separately for each subgroup of patients with myocardial ischemia. The risk rates for smoking categories and the risk functions of systolic pressure and serum cholesterol concentration, as estimated by the log-linear model, were standardized to coronary mortality in east Finland, the age of 55 years, and the means of other confounders in each subgroup of myocardial ischemia. The adjusted rates of risk are thus comparable between the groups in relation to age and location.

Normal deviates and confidence zones were based on the asymptomatic distribution of coefficient estimators.[5] The statistical significance over the smoking categories was tested using likelihood ratio statistics (asymptomatic chi-squared).

Measures of risk for categories or levels of risk factors were expressed in the following terms: (1) *absolute risk* is the actual rate of coronary mortality per 1,000 person-years; (2) *relative risk* is the absolute risk of the "exposed group" divided by the absolute risk of the reference group; (3) *attributable risk* is the difference between absolute risk in the exposed group and the reference group. Relative risk compares the predictive power of different levels of risk factors, and thus is suitable for etiologic appraisals, whereas attributable risk measures potential benefit of intervention.

Results

Total and coronary mortality: Altogether 440 deaths, of which 188 were caused by coronary heart disease, occurred during 20,245 person-years of follow-up study. The crude total mortality was thus 21.7 and the coronary mortality 9.3 per 1,000 person-years. In the 3 groups of patients with myocardial ischemia formed on the basis of screening examinations, the corresponding crude rates of total and coronary mortality were as follows: ischemia 15.1 (255 of 16,897) and 4.7 (79 of 16,897) in the absence of ischemia, 33.1 (125 of 3,774) and 18.5 (70 of 3,774) in ischemic heart disease but no infarction, and 109.7 (60 of 547) and 71.3 (39 of 547) deaths per 1,000 person-years in infarction, respectively. The differences reflect the drastic effect of myocardial ischemia on the risk of death from coronary disease and even from other causes, although the rates in relation to age are not exactly comparable.

Effect of smoking: Tables I to III present the predictive value of smoking habits at entry of the absolute, relative, and attributable risks of coronary death in the various groups of patients with myocardial ischemia, as adjusted by age, location, systolic pressure, and serum cholesterol concentration. There was a statistically significant increase among current cigarette smokers in both the group with no ischemia ($p = 0.003$, Table I) and the group with infarction ($p = 0.01$, Table III), whereas the variation of risk according to smoking did not quite reach statistical significance in the men with ischemic heart disease but without infarction ($p = 0.06$, Table II). No clear dose-response relation to daily cigarette consumption was evident, perhaps because of the small number of cases. Pipe or cigar smokers were excluded from the analysis of the infarction group, because no coronary death occurred during their 17 person-years of follow-up study. In the infarction and nonischemic groups, ex-smokers showed risks intermediate between those of current smokers and those of men who had never smoked, but their risks did not differ significantly from those of men who had never smoked. In the ischemia group, however, ex-smokers and men who had never smoked had similar death rates.

The risk of coronary death *attributable to smoking* was very different in the various categories of myocardial ischemia. For example, the attributable risk of coronary death per 1,000 person-years in men consuming 20 or more cigarettes per day was 4.1 in men without myocardial ischemia, 12.1 in men with ischemia but no infarction, and as high as 70.1 in men with a prior infarction. These rates show the great significance of smoking in the presence of myocardial ischemia when the inherent mortality is high.

Effects of systolic pressure and serum cholesterol: Coronary mortality as a log-linear function of systolic pressure and serum cholesterol concentration in the various subgroups of patients with myocardial ischemia at entry is presented in Figures 1 and 2. The functions have been standardized to the mortality of men aged 55 years in east Finland, being mutually comparable. The relation of systolic pressure and serum cholesterol to coronary mortality proved similar in the

subgroups, as shown by the parallel slopes of the lines in both Figures 1 and 2. However, the association between the risk factors and mortality was statistically significant only for systolic pressure in men with myocardial ischemia but no infarction ($p = 0.01$) and for serum cholesterol in men without ischemia and in those with ischemia but no infarction ($p = 0.02$), whereas the findings remained nonsignificant ($p = 0.1$ to 0.3) in the other groups.

As with smoking, the absolute importance of systolic pressure or serum cholesterol was far greater in men with myocardial ischemia at entry, particularly those with a prior infarction, than in men with no evidence of ischemia. On the basis of the risk functions presented in Figures 1 and 2 and of the means and standard deviations shown in Table IV, the risks attributable to given changes of systolic pressure or serum cholesterol concentration can be estimated. For example, if systolic

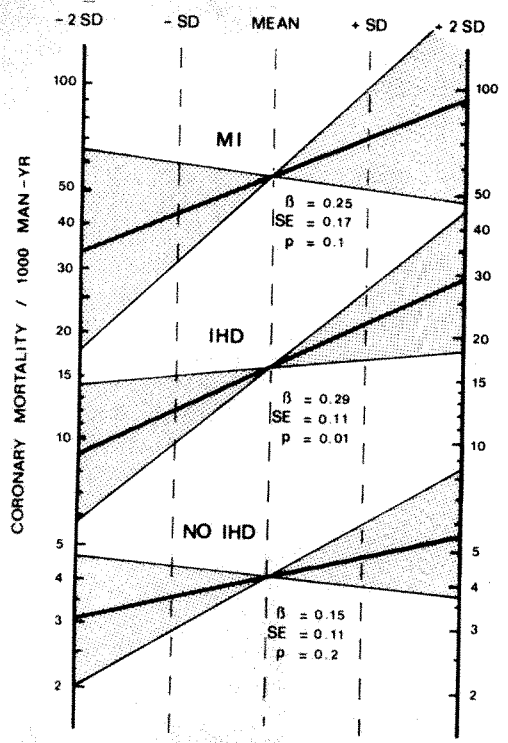

FIGURE 1. Five-year coronary mortality ±95% confidence zone as a function of systolic pressure in men with a prior myocardial infarction (MI), ischemic heart disease (IHD) without infarction, and no evidence of myocardial ischemia (NO IHD) at entry. Mortality rates are estimated by the log-linear model and standardized to the mortality of men aged 55 years in east Finland in relation to age, location, smoking history, and serum cholesterol levels. The means and standard deviations (SD) of systolic pressure are given in Table IV. β = value of coefficient; SE = standard error of β.

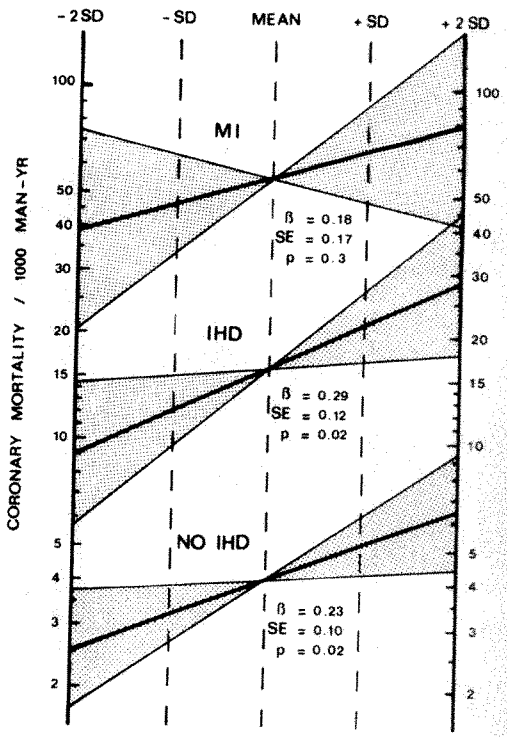

FIGURE 2. Five-year coronary mortality ±95% confidence zone as a function of serum cholesterol concentration in men with a prior myocardial infarction (MI), ischemic heart disease (IHD) without infarction, and no evidence of myocardial ischemia (NO IHD) at entry. Mortality rates are estimated by the log-linear model and standardized to the mortality of men aged 55 in east Finland in relation to age, location, smoking history, and systolic pressure. The means and standard deviations (SD) of serum cholesterol are given in Table IV. β = value of coefficient; SE = standard error of β.

pressure is elevated 30 mm Hg above the mean, the estimate for 5-year coronary mortality increases from 4.1 to 5.2 deaths per 1,000 person-years in men without myocardial ischemia, from 16 to 23 in men with ischemia but no infarction, and from 56 to 73 in men with a prior infarction. Accordingly, an increase in serum cholesterol by 50 mg/100 ml above the mean produces an additional 1.0 coronary death per 1,000 person-years in men without myocardial ischemia, 4.5 deaths in men with ischemia but no infarction, and 9.1 deaths in men with infarction. These estimates, however, are only approximate because of random variation in risk functions.

Additional analyses: The effects of smoking, systolic blood pressure, and serum cholesterol on the adjusted coronary mortality were also separately analyzed for each of the 5-year periods. The results were similar to those in the pooled series except that serum cholesterol predicted mortality during the second and third period only. However, the numbers were too small for definite conclusions to be drawn. Neither did the experience prove sufficient to test the significance of the interactions between the risk factors.

Discussion

Main observations: Smoking, systolic pressure, and serum cholesterol concentration, the classic risk factors of coronary death, were operative even in men who already had clinically manifest myocardial ischemia. Three separate groups of men were analyzed: those with prior myocardial infarction, those with ischemic heart disease but no infarction, and those with no evidence of ischemia. Analysis showed that the risk factors predicted the *relative* likelihood of death from coronary heart disease similarly within the 3 groups. However, the *absolute* impact of these factors on mortality was strong in the presence of myocardial ischemia, especially among men who had had an infarction.

TABLE IV Mean ± Standard Deviation (SD) of Systolic Pressure, Serum Cholesterol Concentration, and Age With 3 Screening Examinations Pooled

	No Ischemia		Ischemic Heart Disease		Myocardial Infarction	
Variable	Mean	SD	Mean	SD	Mean	SD
Systolic pressure (mm Hg)	140.9	19.9	152.2	25.6	155.7	28.6
Serum cholesterol (mg/100 ml)	267.4	53.6	273.4	58.0	278.9	59.2
Age (yr)	54.3	6.6	57.6	6.4	59.3	6.3

Nature of the study: The subjects were middle-aged and older men from rural areas of Finland and were mainly small farmers. The participation rate was exceptionally high, and the follow-up period covered all subsequent deaths. Because ischemic heart disease is very common among Finnish men, the number of cases was sufficient to demonstrate the main findings reliably. The applicability of these findings to other populations has to be shown.

The study was based on *screening examinations of a nonselected population.* Our diagnostic entities of myocardial infarction and ischemic heart disease may thus differ from clinical series of patients, which probably, on the average, contain more severe cases. The predictive value of initial measurements in a prospective study may be blurred with time during a very long follow-up period. Data on risk factors and myocardial ischemia were therefore updated at intervals of 5 years, in order to shorten the time span from the examination to the end-point. The total experience thus consisted of 3 consecutive follow-up periods of the same cohort. In principle, a single 5-year follow-up study of a 3-fold population with the same age structure would have given similar information.

Risk factors and survival in ischemic heart disease: In several studies[6–9] cigarette smoking proved to significantly worsen the long-term prognosis of patients who survive after myocardial infarction. Serum cholesterol concentration also has an effect on survival after recovery from infarction,[10] whereas blood pressure is less important.[11] In the present study, all 3 risk factors predicted the survival of men who had already had a myocardial infarction, although the association was statistically significant for smoking only. In our analysis the follow-up period did not start at the time of the infarction. Because the prognosis of the survivors improves with time[12] and myocardial infarction itself may affect the level of risk factors, at least during hospitalization and possibly also later, our results cannot be directly compared with those of others.

So far, little research has been done on the significance of risk factors in men with angina pectoris or minor electrocardiographic findings of ischemic heart disease. In the Whitehall study[13] of British male civil servants, the main risk factors predicted 5-year coronary mortality even during early myocardial ischemia. Yet, subjects with a prior myocardial infarction and mild ischemic heart disease were not analyzed separately. Earlier, the Health Insurance Plan of Greater New York had reported differences in prognosis related to cigarette smoking, blood pressure, and serum cholesterol levels among men with newly diagnosed angina,[14] but the cases were too few to permit confident conclusions. Our findings confirm the significance of classic risk factors in early ischemic heart disease.

The view that the association between major risk factors and ischemic heart disease is causal in nature is supported by its intensity, coherence, consistency between various populations, and dose-response relation.[15] Our epidemiologic findings indicate that smoking, blood pressure, and serum cholesterol are continously involved with development and progression of coronary disease at any stage.

Implications for prevention: Secondary prevention of ischemic heart disease by intervention against risk factors has generally been considered reasonable,[16] although its benefits are less well established than those of primary prevention. Our finding that the risk of coronary death attributable to smoking, systolic pressure, and serum cholesterol in men with clinically manifest ischemic heart disease was much greater than the risk in men without evidence of myocardial ischemia suggests that secondary prevention is of primary importance. However, that the reduction of risk factor levels improves the prognosis remains unconfirmed, even though a favorable effect, such as that achieved through diet, has been suggested.[17–19] Our results also justify the institution of screening for coronary heart disease among middle-aged and older men with subsequent intervention against risk factors.

Our series is too small to demonstrate reliably quantitative relations between various levels of risk factors and survival in subjects with ischemic heart disease. Further longitudinal studies are therefore needed.

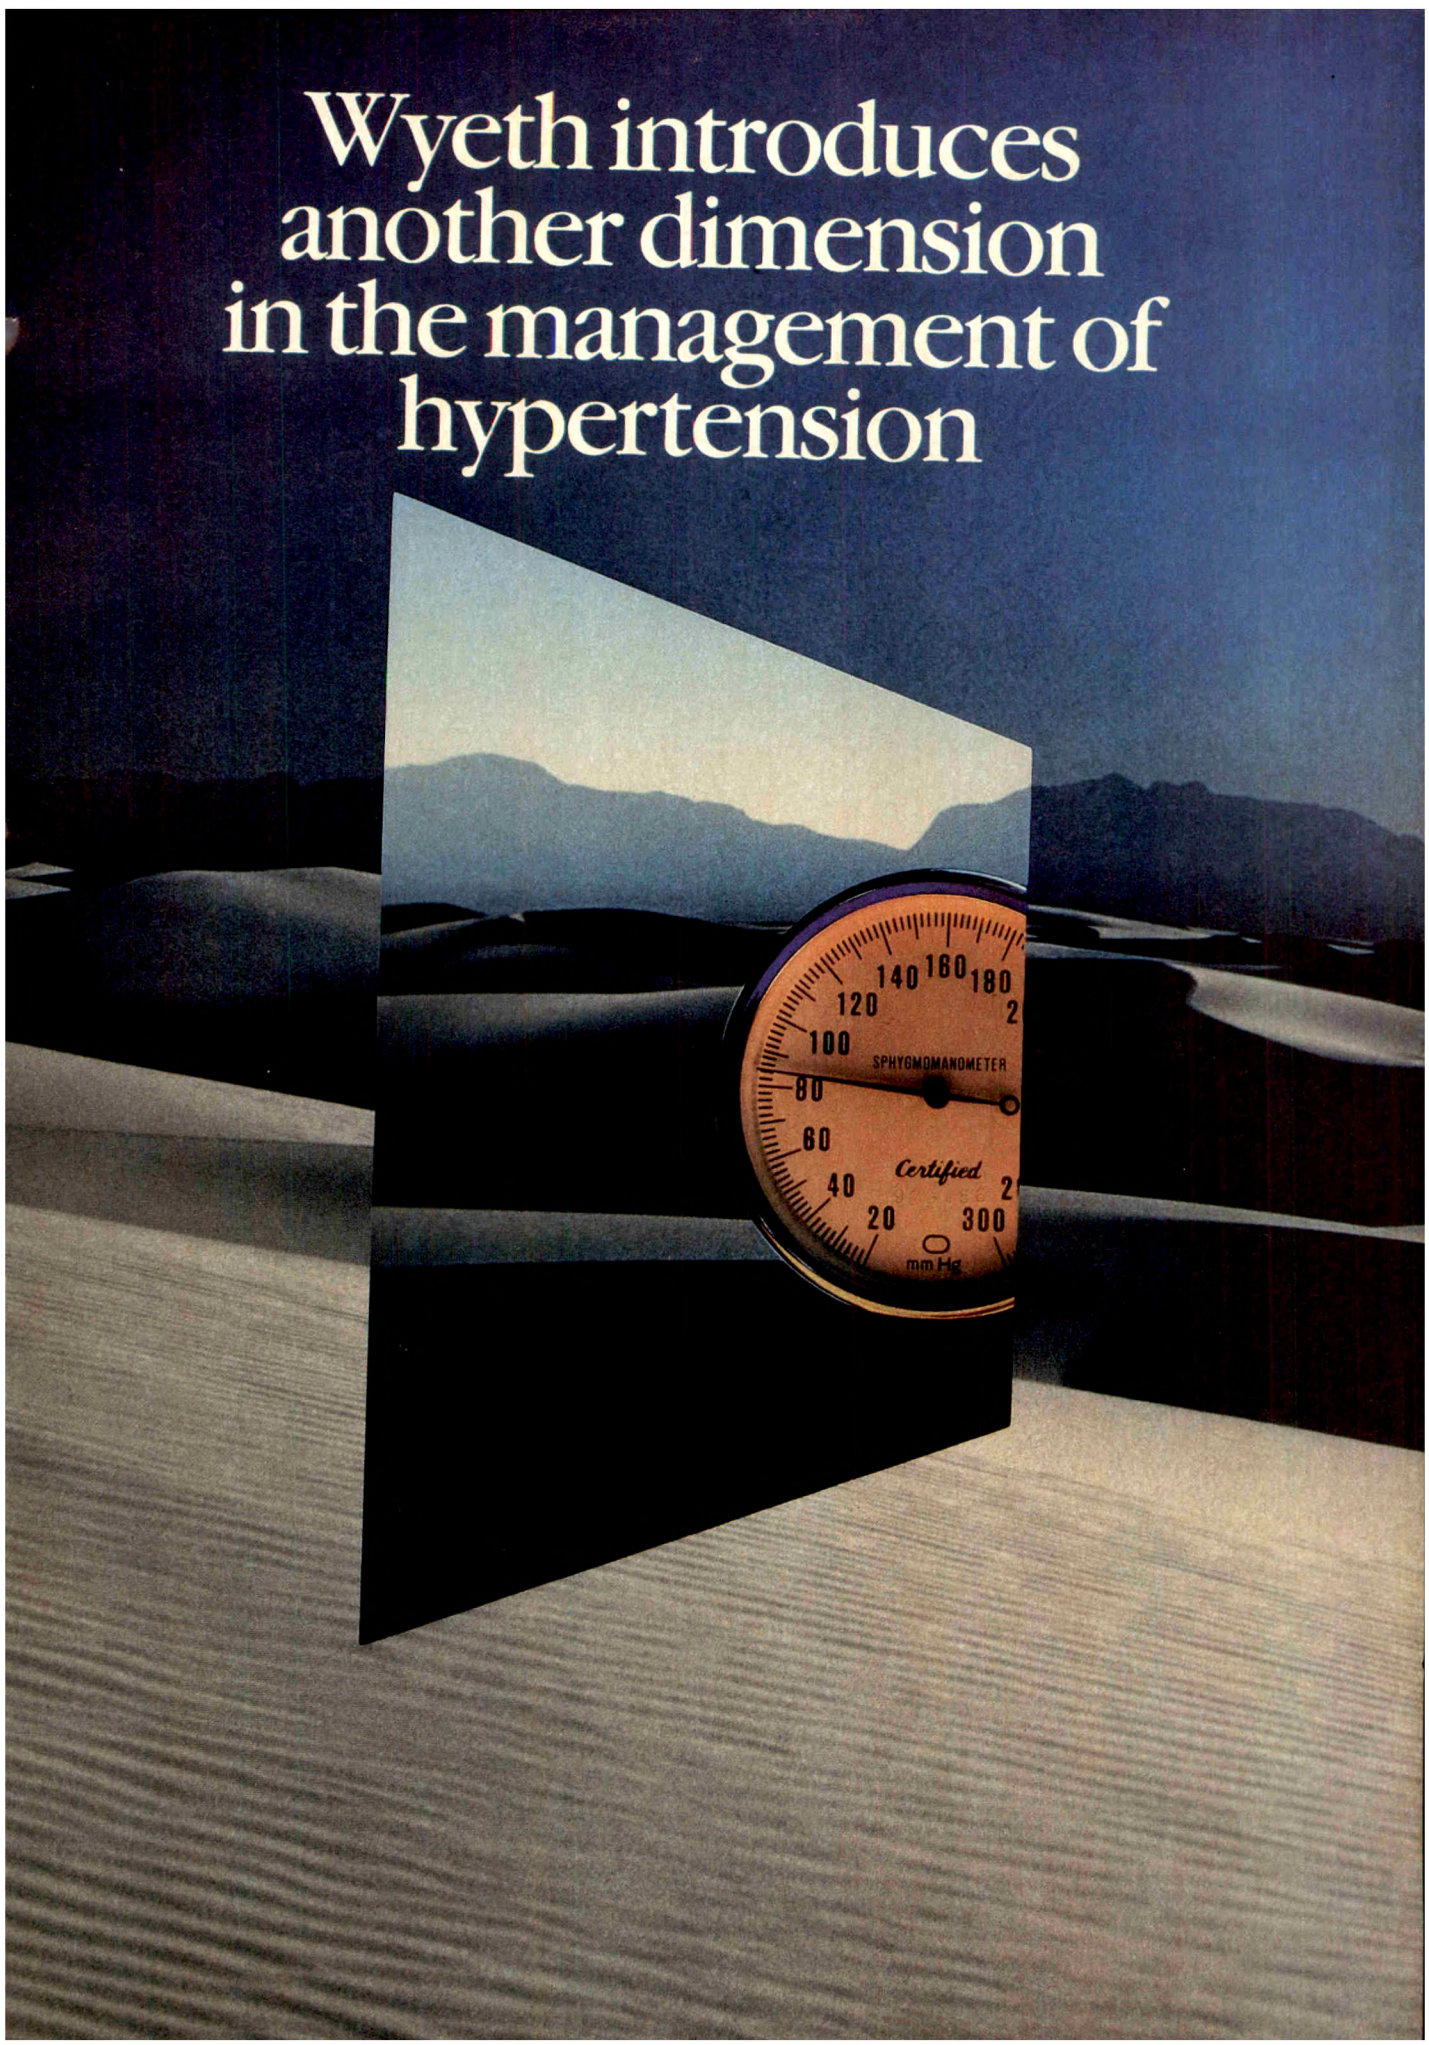
Wyeth introduces another dimension in the management of hypertension



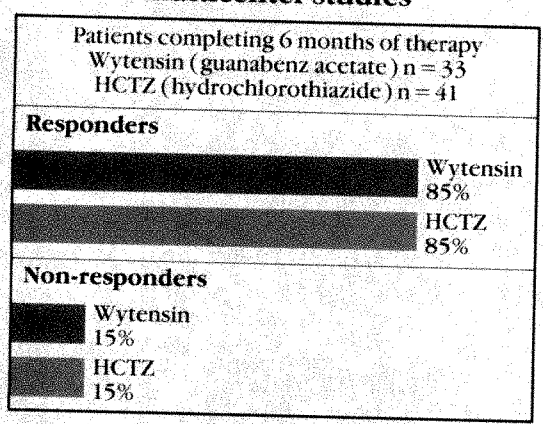
In clinical trials to date:

no potassium depletion
no volume depletion
no hyperlipidemia
no hyperuricemia
no hypercalcemia
no acid-base disturbances
no increased renin activity
no increased catecholamines
no azotemia
no hyperglycemia

Wyeth

Another dimension of management beyond the scope of diuretics

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	HCTZ
potassium	—	↓
renin	—	↑
glucose	—	↑
serum cholesterol	↓	↑
chloride	—	↓
uric acid	—	↑
calcium	—	↑
BUN	—	↑

Wytensin® did not induce long-term cardiovascular risk factors.[1]
Unlike diuretics, Wytensin can be used over the long-term without inducing atherogenic potential risk factors such as hyperlipidemia and hyperglycemia or arrhythmic risk factors such as hypokalemia. With Wytensin therapy a small decrease in heart rate and weight has been observed.

Wytensin® side effects are usually mild and transient.
Although dry mouth and/or drowsiness were the most frequently noted side effects, these subjective complaints usually diminished or disappeared over time. Only 9% of patients discontinued therapy due to drowsiness or dry mouth.
About one third of patients who started Wytensin therapy with 8 mg twice daily experienced these side effects, but starting with 4 mg b.i.d.—the recommended starting dose—reduced both the incidence of these side effects and the consequent dropout rate. In all studies to date, discontinuance of therapy for all side effects occurred in about 15% of patients.

Wytensin® may lower the price the patient pays for therapy.
Because Wytensin did not induce electrolyte and metabolic imbalance, it may save patients trouble and money. A Wytensin prescription reduces the need for frequent laboratory testing as well as for K-sparing agents or K supplements and other agents that frequently cost more than diuretics alone.

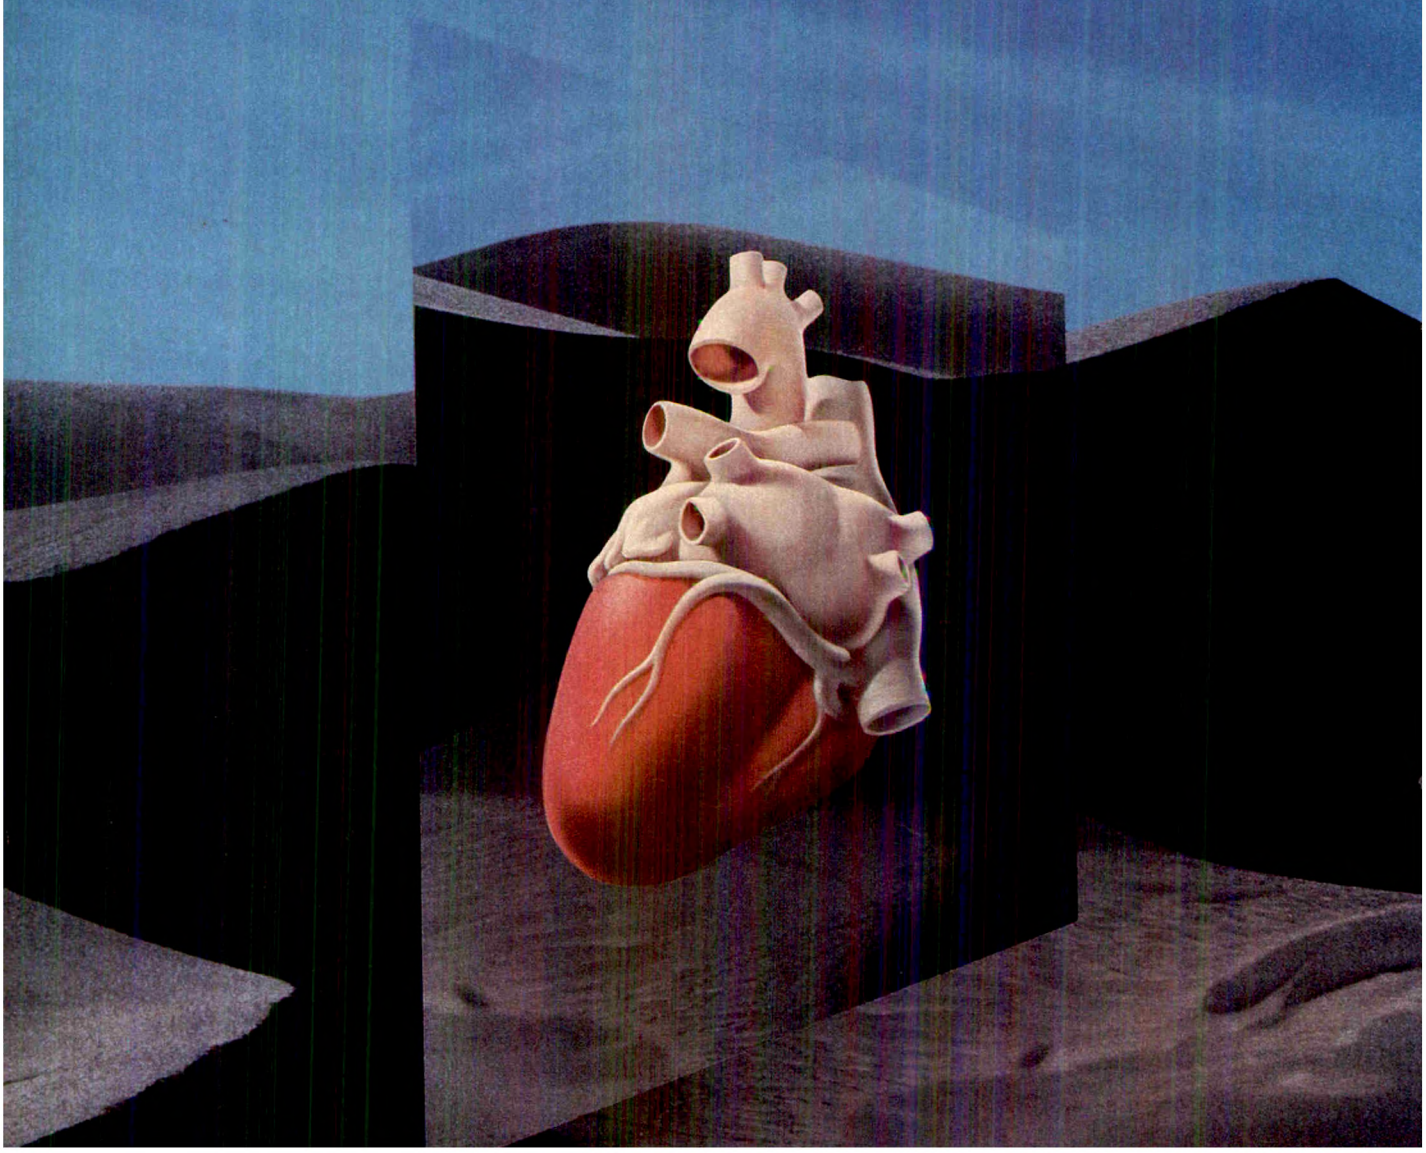
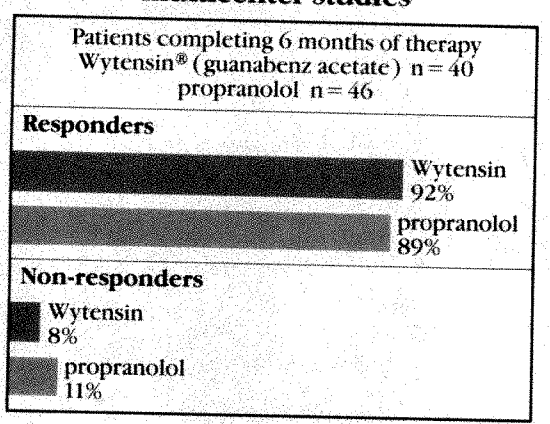
In clinical trials to date:

no contraindications except hypersensitivity
no decrease in cardiac output
no increase in peripheral resistance
no decrease in glomerular filtration rate
no decrease in exercise tolerance
no hyperkalemia
no masking of hypoglycemia
no weight gain
no memory loss
no increase in serum cholesterol
no increase in plasma catecholamines



Another dimension of management beyond the scope of beta-blockers

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	propranolol
potassium	—	↑
serum cholesterol	↓	—
cardiac output	—	↓
glomerular filtration rate	—	↓
peripheral resistance	↓	↑
exercise tolerance	—	↓
plasma catecholamines	↓	↑

Wytensin® lacks the risks of beta-blockade.
Wytensin® is less problematic than beta-blockers, which are contraindicated in many patients and must be used with caution in many others. For instance, exercise intolerance, nightmares, and memory failure can be problems with beta-blockers, and in many black and/or elderly patients, beta-blockade is ineffective.

Wytensin® side effects are usually mild and transient.
The subjective complaints of drowsiness and dry mouth were the most frequently noted side effects and usually diminished or disappeared over time. During initial therapy, patients should be cautioned against driving automobiles or operating dangerous machinery.

Wytensin® can be used in a broader spectrum of hypertensives.
In contrast to beta-blockers, Wytensin has no contraindications except hypersensitivity and is effective regardless of the aging process or racial factors. And, unlike beta-blockers, Wytensin causes a slight decrease in serum cholesterol and maintains potassium balance. Moreover, Wytensin does not cause clinically significant bradycardia or decreased cardiac output. There is no stimulation of vasopressor mechanisms.[2]

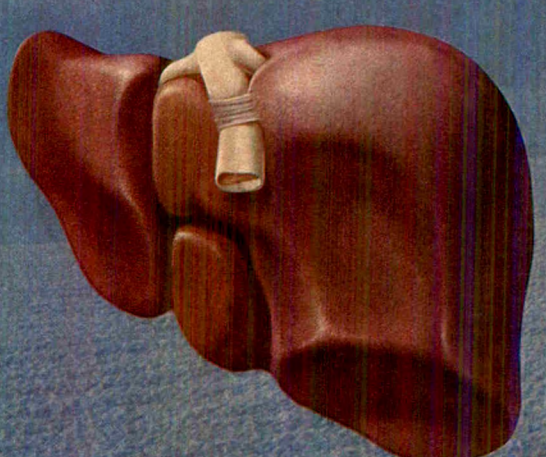
Initial monotherapy in hypertension

See important information on last page.

In clinical trials to date:

no sodium retention
no weight gain
no decrease in GFR

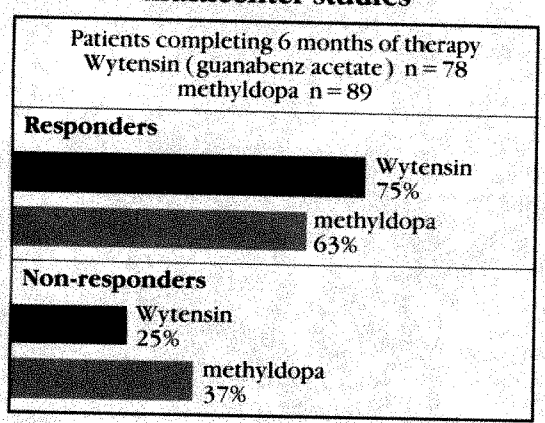
no immunological disturbances
no liver damage
no hemolytic anemia



Wyeth

Another dimension of management beyond the scope of methyldopa

Highly effective in double-blind, multicenter studies



Important homeostatic advantages

	Wytensin	methyldopa
sodium excretion	—	↓
plasma volume	—	↑
weight	↓	↑
glomerular filtration rate	—	↓

Wytensin® does not produce sodium retention or volume expansion.[3]
Methyldopa causes sodium retention and volume expansion with consequent development of drug tolerance. In contrast, drug tolerance has not developed with Wytensin probably because it does not induce retention of sodium and body fluid.

Wytensin® is virtually free of serious adverse reactions.
Unlike methyldopa, Wytensin does not produce immunological blood or liver toxicity or produce a positive Coombs' test. Wytensin also lacks the relatively high incidence of sexual dysfunction or mental depression seen with methyldopa.

Wytensin® side effects are often transient or avoidable.
Patients may experience drowsiness and dry mouth early during Wytensin therapy, but these effects are mostly mild, especially when the initial dosage is 4 mg b.i.d., with the second dose administered **h.s.**

New

WyTensin®

(guanabenz acetate)

Initial monotherapy in hypertension

New Wytensin® (guanabenz acetate) 4 mg b.i.d.

More than 1,400 patients evaluated

No sodium retention

No electrolyte or metabolic risk factors

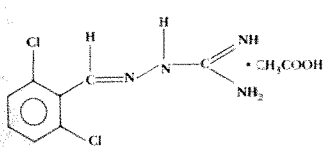
A favorable therapeutic index

Convenient, compliance-enhancing b.i.d. dosage

No contraindications except hypersensitivity

Description

Wytensin (guanabenz acetate), an antihypertensive agent for oral administration, is an aminoguanidine derivative, 2,6-dichlorobenzylideneaminoguanidine acetate, and its structural formula is:



It is an odorless, white to off-white, crystalline substance, sparingly soluble in water and soluble in alcohol, with a molecular weight of 291.14. Each tablet of Wytensin is equivalent to 4 mg or 8 mg of free guanabenz base.

Wytensin is available as 4 or 8 mg tablets for oral administration.

Clinical Pharmacology

Wytensin is an orally active central alpha-2 adrenergic agonist. Its antihypertensive action appears to be mediated via stimulation of central alpha adrenergic receptors, resulting in a decrease of sympathetic outflow from the brain at the bulbar level to the peripheral circulatory system.

PHARMACOKINETICS

In human studies, about 75% of an orally administered dose of Wytensin is absorbed and metabolized with less than 1% of unchanged drug recovered from the urine. Peak plasma concentrations of unchanged drug occur between two and five hours after a single oral dose. The average half-life for Wytensin is about 6 hours. The site or sites of metabolism of Wytensin and the consequences of renal or hepatic insufficiency on excretion of Wytensin or its metabolites have not been determined. The effect of meals on the absorption of Wytensin has not been studied.

PHARMACODYNAMICS

The onset of the antihypertensive action of Wytensin begins within 60 minutes after a single oral dose and reaches a peak effect within two to four hours. The effect of an acute single dose is reduced appreciably six to eight hours after administration, and blood pressure approaches baseline values within 12 hours of administration.

The acute antihypertensive effect of Wytensin occurs without major changes in peripheral resistance, but its chronic effect appears to be a decrease in peripheral resistance. A decrease in blood pressure is seen in both the supine and standing positions without alterations of normal postural mechanisms, so that postural hypotension has not been observed. Wytensin decreases pulse rate by about 5 beats per minute. Cardiac output and left ventricular ejection fraction are unchanged during long-term therapy.

With effective control of blood pressure in hypertensive patients, Wytensin has not demonstrated any significant effect on glomerular filtration rate, renal blood flow, renal sodium or potassium excretion, renal concentrating ability, body fluid volume, or body weight. In clinical trials of six to thirty months, hypertensive patients whose blood pressure was controlled with Wytensin lost one to four pounds of body weight. The mechanism of this weight loss has not been established. Tolerance to the antihypertensive effect of Wytensin has not been observed.

During long-term administration of Wytensin, there is a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. Plasma norepinephrine, serum dopamine beta-hydroxylase, and plasma renin activity are decreased during chronic administration of Wytensin. No changes in serum electrolytes, uric acid, blood urea nitrogen, calcium, or glucose have been observed.

Wytensin and hydrochlorothiazide have been shown to have at least partially additive effects in patients not responding adequately to either drug alone.

Indications and Usage

Wytensin is indicated in the treatment of hypertension. It may be employed alone or in combination with a thiazide diuretic.

Contraindication

Wytensin is contraindicated in patients with a known sensitivity to the drug.

Precautions

1. Sedation: Wytensin causes sedation or drowsiness in a large fraction of patients. When Wytensin is used with centrally active depressants, such as phenothiazines, barbiturates, and benzodiazepines, the potential for additive sedative effects should be considered.

2. Patients with vascular insufficiency: Wytensin, like other antihypertensive agents, should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or severe hepatic or renal failure.

3. Rebound: Sudden cessation of therapy with central alpha agonists like Wytensin may rarely result in "overshoot" hypertension and more commonly produces an increase in serum catecholamines and subjective symptomatology.

INFORMATION FOR PATIENTS

Patients who receive Wytensin should be advised to exercise caution when operating dangerous machinery or driving motor vehicles until it is determined that they do not become drowsy or dizzy from the medication. Patients should be warned that their tolerance for alcohol and other CNS depressants may be diminished. Patients should be advised not to discontinue therapy abruptly.

LABORATORY TESTS

In clinical trials, no clinically significant laboratory test abnormalities were identified during either acute or chronic therapy with Wytensin. Tests carried out included CBC, urinalysis, electrolytes, SGOT, bilirubin, alkaline phosphatase, uric acid, BUN, creatinine, glucose, calcium, phosphorus, total protein, and Coombs' test. During long-term administration of Wytensin, there was a small decrease in serum cholesterol and total triglycerides without any change in the high-density lipoprotein fraction. In rare instances an occasional nonprogressive increase in liver enzymes has been observed. However, no clinical evidence of hepatic disease has been found.

DRUG INTERACTIONS

Wytensin has not been demonstrated to cause any drug interactions when administered with other drugs, such as digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, the potential for increased sedation when Wytensin is administered concomitantly with CNS depressant drugs should be noted.

DRUG/LABORATORY TEST INTERACTIONS

No laboratory test abnormalities were identified with the use of Wytensin.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY

No evidence of carcinogenic potential emerged in rats during a two-year oral study with Wytensin at doses up to 9.5 mg/kg/day, i.e., about 10 times the maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, Wytensin at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in the number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those which were lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, Wytensin produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats administered high oral doses (9.6 mg/kg) of Wytensin, suggesting an impairment of fertility. The fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by the decreased pregnancy rate of their mates, even though the females received Wytensin only during the last third of pregnancy.

PREGNANCY

Pregnancy Category C

WYTENSIN MAY HAVE ADVERSE EFFECTS ON THE FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice has indicated a possible increase in skeletal abnormalities when Wytensin is given orally at doses of 3 to 6 times the maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral Wytensin administration to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies of Wytensin in rats have shown slightly decreased live-birth indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. Wytensin should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

NURSING MOTHERS

Because no information is available on the excretion of Wytensin in human milk, it should not be administered to nursing mothers.

PEDIATRIC USE

The safety and effectiveness of Wytensin in children less than 12 years of age have not been demonstrated. Therefore, its use in this age group cannot be recommended at this time.

Adverse Reactions

The incidence of adverse effects has been ascertained from controlled clinical studies conducted in the United States and is based on data from 859 patients who received Wytensin for up to 3 years. There is some evidence that the side effects are dose-related.

The following table shows the incidence of adverse effects occurring in at least 5% of patients in a study comparing Wytensin to placebo, at a starting dose of 8 mg b.i.d.

Adverse Effect	Placebo (%) n = 102	Wytensin (%) n = 109
Dry mouth	7	28
Drowsiness or sedation	12	39
Dizziness	7	17
Weakness	7	10
Headache	6	5

In other controlled clinical trials at the starting dose of 16 mg/day in 476 patients, the incidence of dry mouth was slightly higher (38%) and that of dizziness was slightly lower (12%), but the incidence of the most frequent adverse effects was similar to the placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, the incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects were reported during clinical trials with Wytensin but are not clearly distinguishable from placebo effects and occurred with a frequency of 3% or less:

Cardiovascular—chest pain, edema, arrhythmias, palpitations.
Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort.
Central nervous system—anxiety, ataxia, depression, sleep disturbances.
ENT disorders—nasal congestion.
Eye disorders—blurring of vision.
Musculoskeletal—aches in extremities, muscle aches.
Respiratory—dyspnea.
Dermatologic—rash, pruritus.
Urogenital—urinary frequency, disturbances of sexual function.
Other—gynecomastia, taste disorders.

Drug Abuse and Dependence

No reported dependence or abuse has been associated with the administration of Wytensin.

Overdosage

Accidental ingestion of Wytensin caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and administration of pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both patients.

Since experience with accidental overdosage is limited, the suggested treatment is mainly supportive while the drug is being eliminated from the body and until the patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. An adequate airway should be maintained and, if indicated, assisted respiration instituted. There are no data available on the dialyzability of Wytensin.

Dosage and Administration

Dosage with Wytensin should be individualized. A starting dose of 4 mg twice a day is recommended, whether Wytensin is used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg per day every one to two weeks, depending on the patient's response. The maximum dose studied to date has been 32 mg twice daily, but doses as high as this are rarely needed.

How Supplied

Wytensin® (guanabenz acetate) Tablets, Wyeth®, are available in the following dosage strengths:

4 mg, NDC 0008-0073, white, round tablet marked "WYETH" and "73", in bottles of 100.

8 mg, NDC 0008-0074, white, round, scored tablet marked "WYETH" and "74", in bottles of 100.

Keep bottles of Wytensin Tablets tightly closed.
Dispense in tight containers.
Protect from light.

Issued August 17, 1982

Cold Pressor Thallium-201 Myocardial Scintigraphy in the Diagnosis of Coronary Artery Disease

MASOOD AHMAD, MD, FRCP(C), JERZY P. DUBIEL, MD, and HELMUT HAIBACH, MD

Thallium-201 myocardial scintigraphy was performed during cold pressor stimulation in 36 patients aged 37 to 69 years. Thirty-one patients had coronary artery disease and 5 patients did not, as confirmed by coronary cineangiography. Thallium-201 (1.5 to 2 mCi) was injected at 30 seconds of the cold pressor stimulation. The product of systolic pressure × heart rate increased from a baseline of 77.4 ± 16 (standard deviation [SD]) to 103.6 ± 17 at 30 seconds of the cold pressor test ($p < 0.0005$). Transient perfusion deficits developed in 24 of 31 patients with coronary artery disease (sensitivity 77%), and all 5 patients without coronary artery disease had normal scintigrams. The sensitivity in detecting coronary artery disease was 40% in patients with 1 vessel disease, 91% in patients with 2 vessel disease, and 100% in patients with 3 vessel disease. Exercise electrocardiograms (available in 29 of 36 patients) were positive for ischemia in 18 of 24 patients with coronary artery disease and in 1 of 5 patients without coronary artery disease (sensitivity 75% and specificity <80%). Exercise thallium-201 scintigrams, obtained in 16 patients, were positive in 11 patients with coronary artery disease and positive cold pressor thallium-201 scintigrams. Five patients without coronary artery disease and with normal cold pressor thallium-201 scintigrams had normal exercise thallium-201 scintigrams. Coronary cineangiography performed during cold pressor stimulation in 6 patients who had positive cold pressor and exercise thallium-201 scintigrams did not show coronary spasm. Our data indicate that cold pressor thallium-201 scintigraphy offers promise as a noninvasive test in the diagnosis of coronary artery disease and may be used in patients in whom exercise testing is not feasible.

Thallium-201 myocardial scintigraphy with exercise has proved a valuable noninvasive technique in the evaluation of myocardial perfusion in patients with coronary artery disease.[1] Many sick and debilitated patients, however, are unable to perform the exercise needed for the test, and some have symptoms that are not related to exercise. The cold pressor test results in a rapid increase in blood pressure and induces abnormalities in left ventricular function in patients with coronary artery disease.[2,3] In the present study, cold pressor stimulation was examined for the first time as an alternative to the standard exercise stress test in the scintigraphic evaluation of myocardial perfusion.

Methods

Patient population: The study group consisted of 36 patients (aged 37 to 69 years) whose coronary anatomy had been studied by coronary angiography. The patients were selected from a population being evaluated for chest pain syndromes and for possible coronary artery bypass surgery. Typical angina pectoris, brought on by exertion and relieved by rest and nitrates, was present in 30 patients. Six patients presented with chest pain that was atypical either in location or in its relation to exertion and nitrates. The duration of symptoms ranged from 1 to 11 years. Thirty-one patients were taking nitrates for relief of chest pain. Five patients were being treated with propranolol (40 to 180 mg daily) and 4 patients were taking digoxin (0.25 mg daily) and diuretics at the time of the study. Five patients had evidence of previous myocardial infarction, transmural in 2 patients and nontransmural in 3. Seven patients had ventricular arrhythmias (premature ventricular contractions) and nonspecific ST-T wave changes. There was evidence of cardiomegaly in 3 patients. All patients underwent standard left heart catheterization, and coronary

cineangiograms were obtained in multiple projections. Left ventricular and coronary cineangiograms were interpreted by a single experienced observer. Coronary artery disease was diagnosed when ≥50% luminal diameter narrowing was observed in at least 1 major coronary artery. The interpretation of coronary angiograms was based on the observer's visual estimate of the degree of luminal narrowing. Thirty-one patients had significant coronary artery disease. Triple vessel coronary artery disease was present in 10 patients, double vessel disease in 11 patients, and single vessel disease in 10 patients. In the remaining 5 patients, coronary angiograms were read as normal based on no disease in 3 patients and <50% luminal diameter narrowing of 1 of the major vessels in 2 patients. Greater than 50% narrowing of the left main coronary artery was present in 2 patients with triple vessel disease. Seven patients with triple vessel disease had areas of ventricular wall motion abnormality, and small discrete left ventricular aneurysms were present in 2 of these 7 patients. Two patients with double vessel disease also had areas of left ventricular wall motion abnormality. The left ventricular ejection fraction of 5 patients (4 with triple vessel and 1 with double vessel disease) was depressed and ranged from 35 to 45%. The resting left ventricular end-diastolic pressure in these 5 patients was abnormally elevated. In 5 patients, the left ventricular ejection fraction was mildly depressed, ranging from 45 to 55%, and the remaining 26 patients had a normal resting ejection fraction.

Twenty-nine patients (24 with and 5 without coronary artery disease) were able to complete a symptom-limited maximal exercise stress test using Bruce's[4] multistage treadmill protocol. The patient's heart rate, blood pressure, and electrocardiogram (modified V_5 electrode) were monitored throughout the exercise. In 13 patients, the exercise stress test was carried out at the time of hospitalization for cardiac catheterization. In the remaining 16 the test had been performed for the evaluation of chest pain within the 6 months before hospitalization. Seven patients did not have an exercise stress test, either because of an unstable clinical state (4 patients) or because of severe peripheral vascular disease (3 patients). All exercise stress test electrocardiograms were interpreted by a single experienced observer without knowledge of the patients' angiographic or scintigraphic data. Exercise stress test was interpreted as positive when >1 mm S-T segment depression was observed in the exercise electrocardiogram.

Cold pressor thallium-201 scintigraphy: All patients underwent thallium-201 myocardial scintigraphy after the cold pressor test. After the baseline electrocardiogram and blood pressure were recorded, the patient's one hand was suddenly immersed up to the level of the styloid process in a bucket of ice water (temperature 0 to 2°C) for 2 to 3 minutes. The electrocardiogram and blood pressure were monitored continuously. Thallium-201 (1 to 2 mCi) was injected intravenously through a previously established intravenous line between 30 and 60 seconds of the cold pressor test. This time of injection was chosen because maximal changes in heart rate and blood pressure occurred at 30 seconds of cold exposure in all patients. In addition, this time of injection allowed the maximal uptake of thallium-201 by the myocardium to occur while the patient was still under cold pressor challenge. Imaging was begun within 5 to 10 minutes of the termination of the cold pressor test. An Ohio Nuclear Series 120 Gamma Camera and a high resolution collimator were used for imaging. Polaroid scintiphotographs with counts of 300,000 to 400,000 were obtained in the anterior, 45° left anterior oblique, and left lateral views. Data were also recorded on magnetic tape for subsequent analysis on a PDP-11 digital computer. Follow-up thallium-201 scintigrams were obtained in the same projections 4 hours after the initial scintigrams. Image processing and interpretations were carried out as previously described.[5] All interpretations were based on polaroid scintiphotographs. Computer-processed images were used for further confirmation of the results. Briefly, thallium-201 scintigrams were interpreted as abnormal when a discrete area of decreased or absent activity was noted. Partial or complete resolution of the scintigraphic defect from early images to follow-up examination was required before the defect was labeled as related to stress.

According to the method of Richie et al,[1] the anatomic location of the perfusion defect was determined from the left anterior oblique view in which the medial wedge represents the left anterior descending coronary distribution (an anterior defect); the posterolateral wedge, the circumflex coronary distribution (a posterior defect); and the inferior wedge, the posterior descending coronary distribution (an inferior defect). With the exception of the perfusion defects at the apex, image abnormalities were not considered defects unless they were visualized in the left anterior oblique view. Each set of early and follow-up scintigrams was read independently by 2 observers without knowledge of the clinical or cineangiographic data. The 2 independent observers agreed completely regarding the presence or absence of perfusion deficits in all but 8 instances. The disagreements in these 8 instances were resolved by adding a third observer and the final interpretation was then based on a consensus of 2 of 3 observers.

Thallium-201 scintigraphy with exercise: Within 1 week of cold pressor thallium-201 scintigraphy, 16 patients were exercised on a treadmill to a symptom-limited maximum. Heart rate and blood pressure were monitored continuously. Thallium-201 (1.5 to 2 mCi) was injected 1 minute before termination of the exercise. Scintigrams were obtained immediately after the exercise and 4 to 6 hours later. Analysis and interpretation of the scintigrams were carried out as described in the preceding section. Thallium-201 scintigrams during exercise could not be obtained in 13 patients, because 7 urgently required coronary bypass surgery and 6 others were unwilling to participate in an additional exercise test.

Thallium-201 scintigraphy at rest: To exclude the possibility that transient deficits of myocardial perfusion might have occurred independent of the stress intervention, we performed resting thallium-201 scintigraphy in 6 patients with triple vessel disease. All of these 6 patients had had transient perfusion deficits after the cold pressor and exercise tests. Thallium-201 scintigraphy was then performed at rest, without intervention, and repeated 4 hours later.

Coronary cineangiography during the cold pressor test: The mechanism of ischemia during the cold pressor test was examined in 6 patients and the possibility of coronary spasm as a cause was evaluated by performing coronary cineangiography before and during the cold pressor challenge. Coronary cineangiograms obtained before and during the cold pressor test were compared.

Results

A positive electrocardiographic exercise stress test was recorded in 18 of 24 patients with coronary artery disease and in 1 of 5 patients without coronary artery disease (a sensitivity of 75% and specificity of 80% for the whole group). Sensitivity was low (50%) in patients with single vessel disease. The patient with normal coronary angiograms and false-positive exercise stress test was not receiving digoxin or diuretics at the time of the test.

TABLE I Thallium-201 Scintigraphic and Exercise Electrocardiographic Data

	Total Patients (n)	Systolic Pressure × Heart Rate (Mean ± SD)		Patients (n) With Positive Changes/Total Patients				
		Baseline	Thallium-201 Injection*	1 Vessel CAD	2 Vessel CAD	3 Vessel CAD	No CAD	Sensitivity†
Cold pressor thallium-201 scintigraphy	36	77.4 ± 16	103.6 ± 17.0‡	4/10	10/11	10/10	0/5	77%
Exercise ECG	29	75.2 ± 11.7	210.8 ± 8.3‡	5/10	5/6	8/8	1/5	75%

Resting thallium-201 scintigraphy	6	77.6 ± 8.2	77.6 ± 8.2	. . .	. . .	1/6	. . .	. . .

* Injections were performed at 30 to 60 seconds of the cold pressor test during cold pressor scintigraphy, at peak exercise during exercise scintigraphy, and at rest during resting scintigraphy. † Sensitivity figures are for total patients. ‡ $p < 0.0005$ compared with baseline.
CAD = coronary artery disease; ECG = electrocardiogram.

The scintigraphic data are presented in Table I. After the cold pressor test, an increase in the systolic blood pressure × heart rate product (double product) was observed in all patients. The mean double product for the group was significantly higher at 30 seconds of the cold pressor test ($p < 0.0005$) (*t* test for paired data). After the initial increase in the double product at 30 seconds, no further significant increase occurred at 2 minutes of the cold pressor test. Both heart rate and blood pressure returned to baseline values within 5 minutes of the termination of the test in all patients. In addition to the changes in the double product, angina developed in 4 patients during the test and a >1 mm S-T segment depression in the electrocardiogram was observed in 3 of these 4 patients. In 5 patients, frequent unifocal premature ventricular contractions were observed during the test with complete resolution after the test. In none of the patients did sustained angina or new changes in the 12-lead electrocardiogram obtained 4 to 6 hours after the test develop.

Transient perfusion deficits were observed in 24 of 31 patients with coronary artery disease (a sensitivity of 77%). The sensitivity for the detection of coronary artery disease was high in patients with double and triple vessel disease (Table I). The location of a perfusion defect generally corresponded to that of a stenotic vessel in all patients with single vessel disease. Transient perfusion deficits, however, did not generally distinguish patients with single vessel disease from those with double and triple vessel disease. Only the most severely ischemic area among the several that may be present in patients with 2 and 3 vessel disease was identified. All 5 patients without coronary artery disease had normal scintigrams. Figure 1 shows representative scintigrams obtained early and late after the cold pressor test.

Thallium-201 scintigrams after symptom-limited maximal exercise stress test were obtained in 16 patients. Eleven patients (6 with triple, 3 with double, and 2 with single vessel disease) had positive scintigrams after exercise. All of these 11 patients also had positive scintigrams after the cold pressor test. The 5 patients with normal coronary cineangiograms had normal exercise scintigrams. The sensitivity level of cold pressor thallium-201 scintigraphy in detecting coronary artery disease was not significantly different from the sensitivity levels obtained during exercise scintigraphy and exercise electrocardiography (chi-square test for inde-

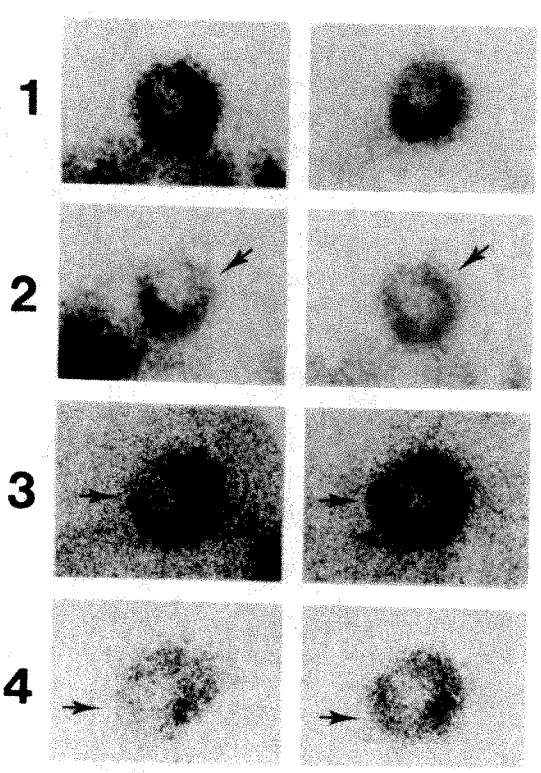

FIGURE 1. Thallium-201 scintigrams (45° left anterior oblique projection), immediately after the cold pressor test (**left**) and 4 hours later (**right**). Normal scintigrams in a patient with normal coronary angiograms (**panel 1**), abnormal scintigrams in patients with single vessel disease (circumflex vessel) (**panel 2**), double vessel disease (left anterior descending and right coronary vessels) (**panel 3**), and triple vessel disease (**panel 4**). **Arrows** point to the areas of transient perfusion deficits.

pendence). The site of the transient perfusion deficits observed in the 45° left anterior oblique cold pressor thallium-201 scintigrams was identical to the site of the perfusion deficits observed in the 45° left anterior oblique exercise thallium-201 scintigram in 8 patients. Anterior perfusion deficits were observed in 6 patients with triple vessel disease, in 1 patient with double vessel disease (left anterior descending and right coronary artery), and in 1 patient with single vessel disease (isolated left anterior descending lesion). Cold pressor scintigraphy induced posterior perfusion deficits in 2 patients with double vessel disease (right coronary and circumflex vessels) whereas with exercise scintigraphy the perfusion deficits appeared in the inferior region. In 1 patient with an isolated high grade (>90%) proximal lesion of a dominant circumflex coronary artery the perfusion deficit was high posterior during the cold pressor test and inferior during the exercise. Among the 6 patients who had thallium-201 scintigraphy performed at rest, only 1 patient showed a mild transient perfusion deficit in the early scintigram in the absence of angina or the electrocardiographic changes of ischemia. The perfusion deficit was smaller than the one observed in the cold pressor thallium-201 scintigram and resolved completely in the follow-up scintigram. No transient deficits of perfusion were observed in the remaining 5 patients. Permanent perfusion deficits were observed in 2 patients with a previous transmural myocardial infarction at rest as well as during the cold pressor scintigraphy. The 3 patients with a previous nontransmural myocardial infarction demonstrated no permanent perfusion abnormality.

The mean double product achieved at 30 seconds of the cold pressor test during coronary cineangiography in 6 patients with coronary artery disease was 101.3 ± 10.24 and was not significantly different from that attained during cold pressor thallium-201 scintigraphy (99.7 ± 9.3) (t test for paired data). Coronary spasm, either focal or generalized, was not detected in any of these 6 patients with positive cold pressor and exercise thallium-201 scintigrams.

Discussion

The cold pressor test is a simple and effective alpha-adrenergic stimulus.[2,3,6] Because a rapid increase in blood pressure and heart rate occurs during cold pressor stimulation, a number of recent investigations have focused on its use as a stress test in patients with coronary artery disease.[3,7,8] Wainwright et al[3] evaluated left ventricular function in normal subjects and in patients with coronary artery disease by performing radionuclide angiography during the cold pressor test. An increase in the left ventricular ejection fraction was reported in normal subjects. In patients with coronary artery disease, reduction in ejection fraction and development of regional wall motion abnormalities were observed. In other studies, increased coronary vascular resistance[7] and angiographic evidence of coronary artery spasm[9] were observed during the cold pressor test. The simple technique of cold pressor stimulation, its effectiveness in challenging the circulatory system, and its apparent innocuous nature led us to investigate its role in evaluating myocardial perfusion in patients with coronary artery disease.

Our preliminary results with cold pressor thallium-201 myocardial scintigraphy were encouraging. Transient perfusion deficits were observed in the thallium-201 scintigrams, after the cold pressor test, in 24 of 31 patients with coronary artery disease, and all 5 patients with normal coronary angiograms had normal scintigrams. As reported with exercise thallium-201 scintigraphy,[1] the detection of coronary artery disease with cold pressor thallium-201 scintigraphy was highest in patients with double and triple vessel disease. All patients with coronary artery disease, who had exercise-induced ischemic changes in the electrocardiograms and in the thallium-201 scintigrams, also had positive cold pressor thallium-201 scintigrams. In 5 patients without coronary artery disease, both cold pressor and exercise thallium-201 scintigraphy were equally specific in ruling out the presence of coronary artery disease.

Of 5 patients with previous myocardial infarction, only 2 patients with a discrete left ventricular aneurysm demonstrated permanent perfusion deficits in addition to the adjacent transient perfusion deficits in the cold pressor thallium-201 scintigram. Ten patients (5 patients with and 5 without previous myocardial infarction) demonstrated depressed left ventricular ejection fractions or regional wall motion abnormality, or both, at the time of cardiac catheterization. Abnormal left ventricular function in patients without evidence of previous myocardial infarction may be related to the development of ischemia at the time of left ventricular angiography or may be due to the presence of an unrecognized previous myocardial necrosis in some of these patients.

Gewirtz et al[10] reported that redistribution of thallium-201 in myocardial segments with initially low thallium-201 uptake may occur at rest, suggesting that transient perfusion abnormalities seen in some patients may be independent of stress intervention. The absence of transient perfusion deficits in the resting thallium-201 scintigrams in 5 of our patients with positive cold pressor thallium-201 scintigrams, however, suggests that scintigraphic changes in these patients were due to the cold pressor test. In 1 patient with triple vessel disease and a mild degree of resting redistribution, the transient perfusion abnormalities were more pronounced during the cold pressor test. The similarity or adjacent nature of the site of the perfusion abnormality in 10 of 11 patients with positive cold pressor and exercise thallium-201 scintigrams further validates the relation of the perfusion deficits to the stress intervention.

There are a few reports in the literature regarding the possible mechanisms involved in altered myocardial perfusion during the cold pressor challenge.[2,9,11] Feldman et al[9] recently reported an increase in coronary vascular resistance in the angiographically defined potentially abnormal regions (>50% coronary artery narrowing) during the cold pressor test. Their study concluded that the increase in coronary resistance was

not due to coronary spasm but possibly to a differential effect of an increased left ventricular end-diastolic pressure on regional blood flow. Thus, it appears that in patients with coronary artery disease, a heterogeneous myocardial perfusion is possible during the cold pressor test, with only modest increases in the double product and without any angiographic evidence of coronary spasm. Mudge et al,[7] however, did not observe increased left ventricular diastolic pressure in some of their patients with increased coronary vascular resistance during cold pressor stimulation. In their study,[7] a decrease in coronary blood flow and an increase in coronary vascular resistance were thought to be due to coronary vascular constriction secondary to alpha-adrenergic stimulation during the cold pressor test. In our study, the double products achieved during cold pressor stimulation were significantly lower than those obtained during exercise, which indicates that an increase in myocardial oxygen demand was probably not the primary mechanism responsible for perfusion abnormalities. The possibility that coronary spasm may have played a role in producing perfusion deficits cannot be excluded. No coronary spasm was detected, however, in 6 patients in whom coronary angiograms were obtained during the cold pressor test.

In summary, our data for the first time provide objective evidence of altered myocardial perfusion during cold pressor stimulation in patients with coronary artery disease. Cold pressor thallium-201 scintigraphy offers promise in detecting abnormal myocardial perfusion and appears to be sensitive in identifying patients with severe coronary artery disease. The limitations of standard exercise thallium-201 scintigraphy became obvious to us during the course of this study in that we were not able to exercise all of our patients. In comparison, the cold pressor challenge was performed with relative ease in all patients. Thus, the cold pressor test may find a diagnostic role in those patients in whom exercise stress test is not feasible. In our experience, cold pressor stimulation is safe and effective and can be performed easily at the patient's bedside. The exact physiologic mechanisms that become operational at the level of the coronary circulation during the cold exposure need further clarification. Our data indicate that further studies in a larger number of patients are warranted in order to define more clearly the sensitivity, specificity, and safety of cold pressor thallium-201 myocardial scintigraphy in patients with coronary artery disease.

Plasma Beta-Thromboglobulin as a Measure of Platelet Activity

Effect of Risk Factors and Findings in Ischemic Heart Disease And After Acute Myocardial Infarction

CHARLES W. PUMPHREY, MD, MRCP and JOAN DAWES, DPh

The plasma concentration of beta-thromboglobulin (BTG), a platelet-specific protein released during platelet aggregation, is considered a sensitive marker of in vivo platelet activity. The mean plasma level in 133 asymptomatic individuals was 32.3 ± 1.1 ng/ml, and there was no difference between those with no risk factors (32.2 ± 1.2 ng/ml, n = 56), those who smoked (31.8 ± 1.8 ng/ml, n = 45), those with hyperlipidemia (32.8 ± 1.7 ng/ml, n = 15), and those exposed to both of these risk factors (34.1 ± 2.7 ng/ml, n = 17). The mean plasma BTG level in 104 patients with symptomatic ischemic heart disease was significantly elevated (40.9 ± 1.4 ng/ml, p <0.01), but there was considerable overlap with normal levels. Although no difference was found between patients with no risk factors (38.1 ± 4.0 ng/ml, n = 13) and those with only 1 risk factor (37.0 ± 1.8 ng/ml, n = 44), patients with 2 or more risk factors had a significantly elevated plasma BTG level (45.2 ± 2.2 ng/ml, n = 47, p <0.01). It is concluded that risk factors themselves do not increase platelet activity, but that patients with vascular disease have activated platelets that may contribute to the progression of the disease. Plasma BTG was also measured serially for 10 days in 29 patients after hospitalization with acute ischemic cardiac pain. Although the median plasma level was elevated above normal there were no acute changes in plasma BTG after either acute infarction (n = 22) or acute ischemia (n = 7), except in 2 patients in whom pericardial friction rubs developed. Thus, measurement of systemic plasma BTG did not detect platelet involvement in acute coronary occlusion or acute ischemia.

Recent studies have highlighted the importance of coronary arterial thrombosis in both acute myocardial infarction and possibly unstable angina pectoris.[1–3] Occlusive arterial thrombosis results from a focus of platelet aggregation, and altered platelet behavior has been well documented in patients with ischemic heart disease.[4–6] However, it remains uncertain whether this alteration in platelet activity causes atherosclerosis and is exacerbated by the presence of known coronary risk factors, or whether it is due to the presence of established arterial disease activating the platelets secondarily.

The plasma level of BTG, a platelet-specific protein released from platelet alpha granules during platelet aggregation, provides an accurate measure of in vivo platelet activity.[7] We report herein the results of measurements of plasma BTG in patients with symptomatic ischemic heart disease and in normal asymptomatic individuals and compare the effect of known coronary risk factors on platelet activity in the 2 groups. We also report the results of studies on changes in plasma BTG in patients after their admission to the Coronary Care Unit with chest pain to identify changes in platelet activity after acute myocardial infarction.

Methods

We studied 104 patients (76 male and 28 female) ranging in age from 27 to 65 years (mean age 51 years). All had a history of current exercise-induced angina pectoris and a resting or exercise electrocardiogram compatible with the diagnosis of ischemic heart disease. Patients with any recent change in

symptoms and those with an elevated creatinine level or additional valve disease, which might affect the plasma BTG level, were excluded. Fifty-five had previously documented myocardial infarction. Sixty-three patients were on beta-blocking drugs and 30 of these were on additional long-acting nitrates or calcium antagonist drugs. Twenty had undergone coronary arteriography and all demonstrated occlusive coronary atherosclerosis.

The smoking habits, blood lipid levels, blood pressure, and family history of ischemic heart disease were documented for each patient. A family history was considered positive for any patient who had a first-degree relative presenting with clinical ischemic heart disease under the age of 60 years. A smoker was defined as a patient who was still smoking at least 10 cigarettes a day. Hyperlipidemia was diagnosed when the serum cholesterol level was >7.0 mmol/liter or the serum triglyceride level was >1.8 mmol/liter in a strict fasting blood specimen despite treatment with diet, drugs, or both. A diastolic pressure >90 mm Hg despite antihypertensive treatment on at least 2 occasions was taken to indicate significant hypertension. No patient had taken aspirin or other anti-inflammatory drugs during the 10 days before sampling.

Blood was taken to determine plasma BTG, platelet count, and serum cholesterol and triglyceride levels during fasting. To prevent ex vivo platelet release and spurious elevation of plasma BTG, all blood samples were carefully collected by 1 of us (CWP), placed in prechilled platelet inhibitor solution, and processed within 1 hour.[7] Samples were assayed for BTG using the double-antibody technique described by Bolton et al,[8] which has an interassay coefficient of variation of 8%.

The results were compared with those of a control group of 101 blood donors (52 male and 49 female subjects) ranging in age from 18 to 64 years (mean 39) who had no history of vascular disease, renal disease, or hypertension and no family history of premature coronary disease. Blood lipid levels were checked at the time of sampling and only those with normal values were included. Their smoking habits were documented. An additional 32 subjects (22 male and 10 female) ranging in age from 22 to 63 years (mean 41) who had no clinical vascular disease but who were attending the Lipid Clinic because of hyperlipidemia were also examined.

In a separate study the platelet activity was measured in 30 patients admitted to the Coronary Care Unit with a diagnosis of possible acute myocardial infarction. Blood for BTG and platelet count was taken usually within 12 hours of the onset of symptoms (minimum 3 hours, maximum 20 hours) and then daily for 10 days or until the patient was discharged. Myocardial infarction was diagnosed on the basis of the conventional criteria of electrocardiographic changes and elevation in cardiac enzyme levels. Medical complications, particularly clinical evidence of deep venous thrombosis, elevated plasma creatinine levels, additional chest pain, pericarditis, or heart failure, were documented. The patients' records were then reviewed at 8 months after discharge from the hospital.

Results in asymptomatic individuals and patients with stable ischemic heart disease are expressed as mean ± standard error. Statistical analysis was carried out using the unpaired Student's t test. Results in patients followed up serially are expressed as a median value, and analysis was carried out using the Wilcoxon rank sum test.

Results

Plasma BTG in clinically asymptomatic subjects: Mean plasma BTG concentrations in relation to the presence of identified risk factors for normal asymptomatic subjects are shown in Figure 1. There was no significant difference between smokers (31.8 ± 1.6 ng/ml, n = 45) and nonsmokers (32.2 ± 1.2 ng/ml, n = 56). Hyperlipidemic subjects with no clinical evidence of vascular disease had normal BTG levels (32.8 ± 1.7 ng/ml, n = 15) and an additional 17 of these individuals who also smoked had a similar mean BTG level (34.1 ± 2.7 ng/ml). No correlation was found between serum cholesterol or triglycerides and plasma BTG in hyperlipidemic subjects, nor was there a difference in BTG concentration among the different classes of hyperlipidemia.

Plasma BTG in patients with stable symptomatic ischemic heart disease: Patients with coronary artery disease, however, had a significantly elevated mean

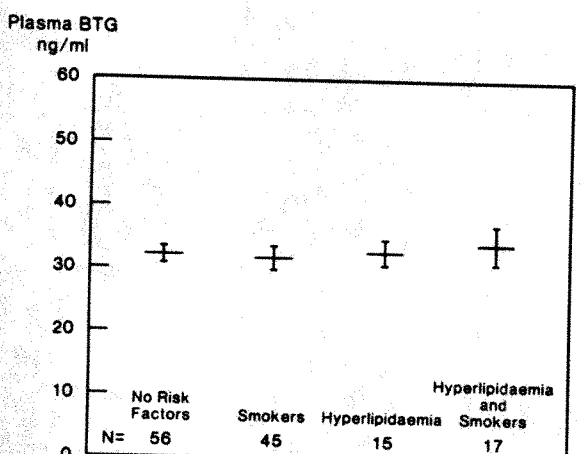

FIGURE 1. Plasma BTG in asymptomatic subjects: relation to risk factors.

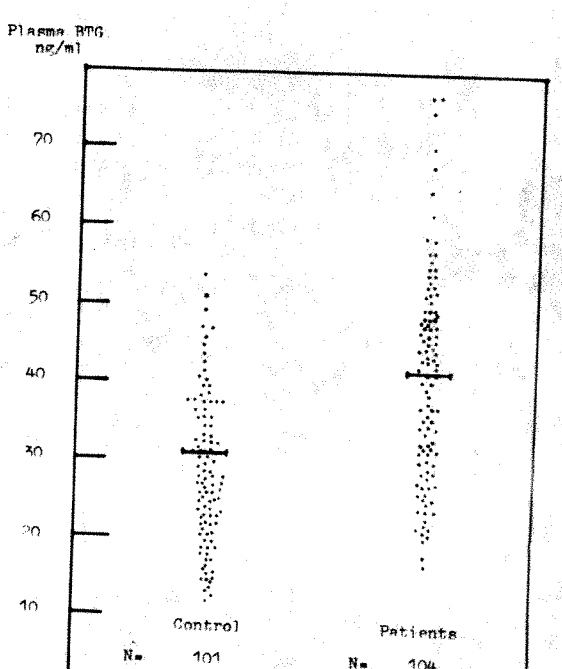

FIGURE 2. Mean and distribution of plasma BTG among control subjects and patients with ischemic heart disease.

plasma BTG level (40.9 ± 1.4 ng/ml, n = 104, p <0.01), although there was considerable overlap with the normal range (Fig. 2). A history of previous myocardial infarction or treatment with beta-blocking drugs or calcium channel-blocking drugs did not affect plasma BTG.

The plasma BTG level was not higher in patients with ischemic heart disease who had a single risk factor compared with those with no identifiable risk factor (Fig. 3). Patients with only a positive family history as a risk factor had a higher mean plasma BTG level than did patients with other risk factors, but for such a small group it was not statistically significant. However, when 2 or more risk factors were present, the mean plasma BTG level was significantly higher (45.2 ± 2.2 ng/ml, n = 47) than that in patients with 1 or no risk factors (37.3 ± 1.6 ng/ml, n = 57, p <0.01) (Fig. 4). No difference was observed between patients with 2 and the small number with 3 (n = 12) or 4 (n = 2) risk factors.

Plasma BTG level after acute chest pain: Of the 30 patients admitted with chest pain, 22 had transmural myocardial infarcts. Seven subsequently had no evidence of infarction and were considered to have unstable angina. One patient was thought to have esophageal pain and was subsequently shown to have normal coronary arteries. Plasma BTG concentrations both in patients with infarct and in those with angina were higher than normal through the period studied, but there was no overall change in median plasma BTG levels with time in either group and no difference between the 2 groups (Fig. 5). The patient with esophageal pain had normal BTG values.

In 2 patients a pericardial friction rub developed which was associated with an acute temporary increase in BTG level, in 1 patient to 74.5 ng/ml and in the other to 95.1 ng/ml. Four patients had additional cardiac pain, with no evidence of infarction extension and no significant alteration in plasma BTG level. In 5 patients heart failure developed with, again, no change in BTG level. In no patient did clinical signs of venous thrombosis, arterial embolism, or an increase in plasma creatinine level develop.

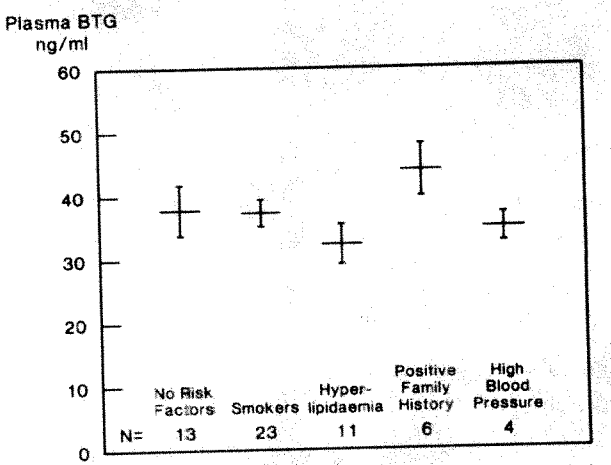

FIGURE 3. Plasma BTG in patients with ischemic heart disease: relation to risk factors.

After 8 months, 2 of the 29 patients had died suddenly (median BTG level on hospital discharge 34.0 ng/ml). One had had another infarct (BTG 37.4 ng/ml) and 8 continued to have angina pectoris (median BTG level 37.9 ng/ml). The other 18 patients were alive with no symptoms (median BTG level 45.1 ng/ml).

Discussion

These results support the concept that platelets function abnormally in patients with ischemic heart disease, evidence for which includes both increased in vitro platelet aggregation and accelerated in vivo platelet consumption.[4-6,9,10] Although the mean age of the control subjects was lower than that of the study group, age is not an independent determinant of plasma BTG levels.[7] The increased platelet activity in our patients was not detectably augmented by single risk

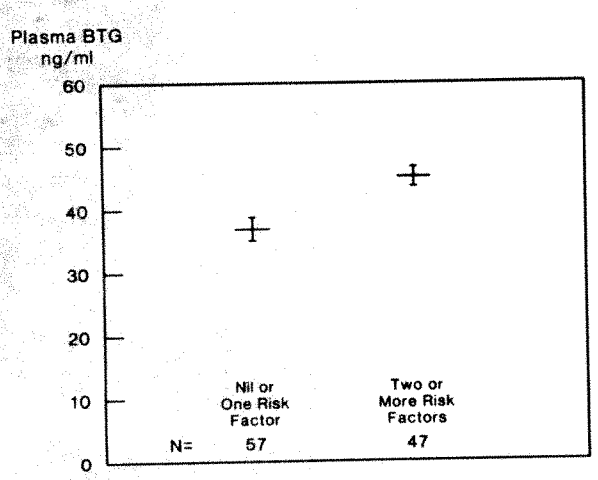

FIGURE 4. Plasma BTG in patients with ischemic heart disease. Comparison of those with 1 or no risk factors to those with 2 or more risk factors.

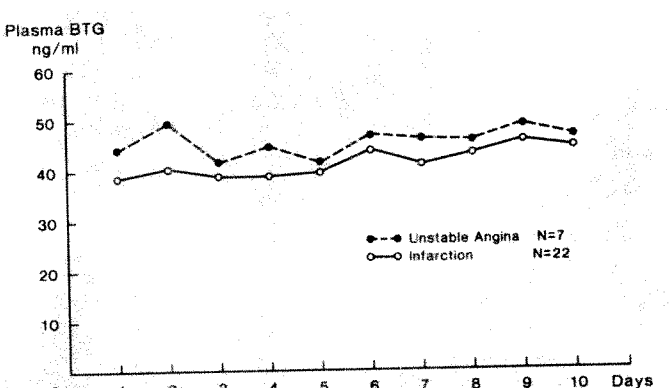

FIGURE 5. Changes in plasma BTG after admission with chest pain (median values).

factors, although in patients with 2 or more risk factors the plasma BTG level was significantly increased. Such risk factors may operate synergistically, and each may have an effect that is not detectable unless these effects are combined. Alternatively, vascular disease may activate platelets which then contribute to further progression of the atherosclerotic process. The increased platelet activation seen in hypertension has been attributed to the existence of established atherosclerosis caused by hypertension rather than to a direct effect on the platelets.[11] Although not all patients who present with cardiac pain have fixed coronary artery stenosis, it was found in the 20 patients who underwent coronary arteriography. Therefore, the higher plasma BTG levels found in our patients with more risk factors may indicate more extensive disease throughout the arterial system.

Our data on normal asymptomatic individuals with the identified coronary risk factors of smoking and hyperlipidemia reinforce this finding. Thus, although our definition of a risk factor was arbitrary, we did not find that the presence of risk factors per se in otherwise healthy subjects significantly affected platelet activity. Although others[12,13] showed altered platelet activity in various types of hyperlipidemia, we found normal plasma BTG levels in asymptomatic patients with hyperlipidemia. In addition, although reduced platelet survival has been reported in apparently healthy smokers,[14] our control subjects who smoked had normal plasma BTG levels and, furthermore, the 17 asymptomatic subjects with both risk factors had no exacerbation of platelet activity. It is likely that platelet survival and plasma BTG do not reflect similar aspects of platelet activity.

Our failure to demonstrate a change in plasma BTG levels after infarction is surprising in view of recent evidence that coronary thrombosis occurs early in the evolution of infarction and may even initiate it.[1,2] Although we were unable to measure plasma BTG levels before infarction, samples were taken as early as 3 hours after the event. If considerable BTG release had been associated with infarction, a subsequent decline in plasma BTG levels from an initial high level should have been observed. Our negative findings suggest that either BTG, with its short half-life, was cleared from the blood before the samples were taken or that the amount of BTG released from a platelet thrombus occluding a coronary artery is not sufficient to cause a measurable increase in the systemic circulation. Furthermore, our findings differ from those of Smitherman et al,[15] who found in some cases very high levels of plasma BTG, although the temporal relation between peak plasma level and infarction was inexact. No reference is made to factors other than ischemia, such as pericarditis, altered renal function, venous thrombosis, or intercurrent infection, which might have contributed to these elevated plasma values.

Similarly, in contrast to another report,[16] we found no increase in plasma BTG levels after episodes of unstable angina. In the few patients who had continuing symptoms after admission, blood samples were taken very shortly after the symptoms were relieved and still no alteration in plasma BTG was observed. Platelet thrombosis is probably not involved in the pathogenesis of unstable angina; alternatively, as already mentioned, systemic venous sampling is not sensitive enough to detect BTG released from platelets in the coronary circulation.

The months after infarction are the period of increased risk of death or reinfarction. We found no correlation between plasma BTG and clinical history during the 8 months after discharge from the hospital. Plasma BTG did not distinguish the 2 patients who died suddenly or those who continued to have angina pectoris, so there is no suggestion that plasma BTG will identify patients with a poor prognosis.

We conclude that elevated plasma BTG levels in patients with ischemic heart disease probably reflect platelet activation by established vascular disease. However, measurement of plasma BTG unable to detect platelet involvement in myocardial infarction or unstable angina pectoris.

Use of QRS Scoring and Thallium-201 Scintigraphy to Assess Left Ventricular Function After Myocardial Infarction

NICHOLAS L. DePACE, MD, ABDULMASSIH S. ISKANDRIAN, MD, A-HAMID HAKKI, MD, SALLY A. KANE, RN, and BERNARD L. SEGAL, MD

To determine the usefulness of the QRS scoring system in predicting left ventricular function, and the correlation between the QRS score, left ventricular ejection fraction, and the size of infarction, patients with acute or chronic infarction were studied by means of 12-lead electrocardiography, rest thallium-201 scintigraphy, and radionuclide angiography.

In patients with acute infarction there was a statistically significant correlation between the QRS score and the left ventricular ejection fraction ($n = 28$, $r = -0.61$, $p < 0.001$), between the thallium score (as a measure of the extent of necrosis) and the left ventricular ejection fraction ($n = 21$, $r = 0.70$, $p < 0.001$), and between the QRS score and the thallium score ($n = 22$, $r = -0.65$, $p < 0.001$). A QRS score of 2 or less separated patients with left ventricular ejection fraction of 40% or greater from those with lower left ventricular ejection fraction ($p < 0.01$).

In patients with chronic infarction there was a wide scatter of ejection fraction for any given QRS score ($n = 41$, $r = -0.51$). In a subset of patients with chronic infarction before they underwent coronary artery bypass, there was still a fair correlation between thallium score and left ventricular ejection fraction ($n = 15$, $r = 0.61$, $p < 0.02$) but not between thallium score and QRS score ($r = 0.03$, $p > 0.05$). In addition, in these patients with chronic infarction who underwent coronary revascularization, there was still a fair correlation between the postoperative thallium score and the postoperative left ventricular ejection fraction ($r = 0.75$, $p < 0.05$) but not between the postoperative thallium score and the postoperative QRS score ($r = 0.02$, $p > 0.05$) or between the QRS score and the ejection fraction ($r = 0.24$, $p > 0.05$).

The size of the defect appears related to the left ventricular ejection fraction in both patients with acute infarction and those with chronic infarction. The QRS scoring system in patients with acute infarction and the size of the thallium defect in patients with acute or chronic infarction can categorize patients into those who have a low, moderate, and normal ejection fraction.

Left ventricular performance is an important factor in determining prognosis in patients with chronic coronary heart disease as well as after acute myocardial infarction.[1–5] Techniques that have been used as prognostic indicators after acute infarction include evaluation of left ventricular ejection fraction and wall motion by radionuclide angiography[6] and evaluation of the size of the scarred or ischemic myocardium by rest thallium-201 scintigraphy.[7] In addition, a specific appearance of the technetium-99m pyrophosphate images has been correlated with poor prognosis.[8] Finally, exercise testing with or without thallium-201 imaging or radionuclide ventriculography has been used to categorize patients after acute infarction in different risk groups.[9,10]

Recently, Palmeri et al,[11] using a QRS scoring system, were able to evaluate left ventricular function in patients with acute myocardial infarction. The QRS scoring system was still fairly accurate in predicting ventricular function up to 1 year after acute infarction in the group of patients they followed up.

We were intrigued by the fact that a QRS score would work at all. If it does, then it is probably due to electrical

forces from viable myocardium. The other noninvasive way to demonstrate viable myocardium is thallium-201 imaging. Furthermore, if there is a change in left ventricular ejection fraction as a result of improvement in myocardial flow by coronary artery bypass surgery, a change of QRS score might be expected as well and probably an improvement in the thallium perfusion defect.

The purpose of this study was to compare the usefulness of the QRS scoring system of 12-lead electrocardiograms with that of resting thallium-201 scintigrams in evaluating the left ventricular function of patients with acute or old myocardial infarction before and after coronary artery bypass.

Methods

We studied 2 groups of patients. The first group consisted of 37 patients with the diagnosis of acute infarction confirmed by typical history, electrocardiographic changes, and elevation in serum enzyme and specific cardiac isoenzyme levels. These patients were admitted to the coronary care unit over a 2-month period. Thallium-201 images at rest are obtained in most patients with acute infarction admitted to our coronary care unit. The second group consisted of 43 patients with a documented history of myocardial infarction (more than 3 months before hospitalization) as determined by history, electrocardiography, and cardiac enzyme levels. Sixteen of the 43 patients subsequently underwent coronary bypass because of angina pectoris.

Standard 12-lead surface electrocardiograms were obtained with a 3-channel Hewlett-Packard recorder at a paper speed of 25 mm/s daily for 3 days and as clinically indicated afterward in 37 patients with acute myocardial infarction. If left ventricular hypertrophy, left anterior hemiblock (QRS axis $\geq -60°$), right or left bundle branch block, ventricular preexcitation, or nonspecific intraventricular delay (QRS ≥ 110 ms) was present on the electrocardiogram at 2 weeks, the patient was withdrawn from the study because the QRS score does not work in these patients. Using these exclusion criteria, we withdrew 8 patients from the study; therefore, 29 patients comprised the study group. Follow-up electrocardiograms were obtained at 2 weeks and compared with radionuclide angiograms performed at that time. Thallium-201 scintigraphy was performed at rest in 22 of the 29 patients 2 weeks after infarction as well. In the remaining 7 patients, thallium images were not obtained because either the patient or the treating physician refused the studies.

A transmural infarct was considered anterior or inferior when new Q waves ≥ 30 ms were present in the precordial leads or lead aVF, respectively. A non-Q-wave infarct was diagnosed when patients had a typical history of infarction with appropriate enzyme elevation, but in whom a Q wave ≥ 30 ms did not develop in the electrocardiogram.

The QRS scoring system was based on the system developed by Selvester et al.[12,13] Q- and R-wave durations and R/Q and R/S amplitudes and ratios in 10 of 12 standard electrocardiographic leads were analyzed (Table I). QRS scores could range from a minimal value of 0 to a theoretical maximum of 29 points.

In patients with chronic infarction, radionuclide angiograms were not available soon after acute infarction. Each patient, however, subsequently underwent electrocardiography and radionuclide angiography. These patients were consecutive patients being evaluated in the nuclear cardiology laboratories for symptoms of angina pectoris. Sixteen of the 43 patients

TABLE I Criteria for Determining Point Score in the QRS Scoring System

Lead	Criteria (Number of Points)		Maximal Points
	Duration	Amplitude Ratio	
I	Q $\geq$30 ms (1)	R/Q $\leq$1 (1)	2
II	Q $\geq$40 ms (2) Q $\geq$30 ms (1)		2
aVL	Q $\geq$30 ms (1)	R/Q $\leq$1 (1)	2

subsequently underwent coronary artery bypass surgery. In 15 of the 16 patients, thallium-201 images at rest were also available preoperatively. Ten to 14 days after surgery, electrocardiography, thallium-201 imaging at rest, and radionuclide angiography at rest were repeated in all but 1 of these 15 patients.

Radionuclide angiography at rest was performed by means of a first-pass technique with a computerized multicrystal gamma camera (Baird-Atomic Systems-77) equipped with a 1-inch (2.54 cm) parallel-hole collimator positioned anterior to the precordium. The study was inadequate in 1 patient because of a poor bolus injection. The technique for measuring the ejection fraction has been described in detail from this[14] and other laboratories.[15]

In a previous study we showed an excellent correlation between radionuclide-derived ejection fractions and similar measurements obtained during cardiac catheterization.[14] The technique for thallium imaging was previously described in reports from this laboratory.[16–20] Quantitative analysis of the thallium images was performed by the perimetric method, as previously described from this laboratory.[18,19] The size of the thallium-201 defect was determined by measuring the perimeter with a computerized Hewlett-Packard 982A digitizer and expressing it as a percentage of the total left ventricular perimeter in each projection (Fig. 1). The region of the valve was excluded. This method is similar to that used by Field et al[3] in assessing the extent of akinetic-dyskinetic segments by means of left ventriculography. The percentage of the average abnormal perimeter was determined from 3 projections.

We also assessed the thallium scans by a scoring system. The image in each of the 3 projections was divided into 3 segments. Each segment was subjectively scored as follows: a score of 0 indicated minimal or no uptake; a score of 1 indicated severe reduction in uptake; a score of 2 indicated a moderate (but definite) reduction in uptake; a score of 3 indicated a mild (thus equivocal) reduction in uptake; and, finally, a score of 4 indicated normal uptake. Because the apex of the left ventricle usually has less thallium uptake than the remaining segments, presumably because the apex is thinner than the rest of the myocardium, we multiplied the score in

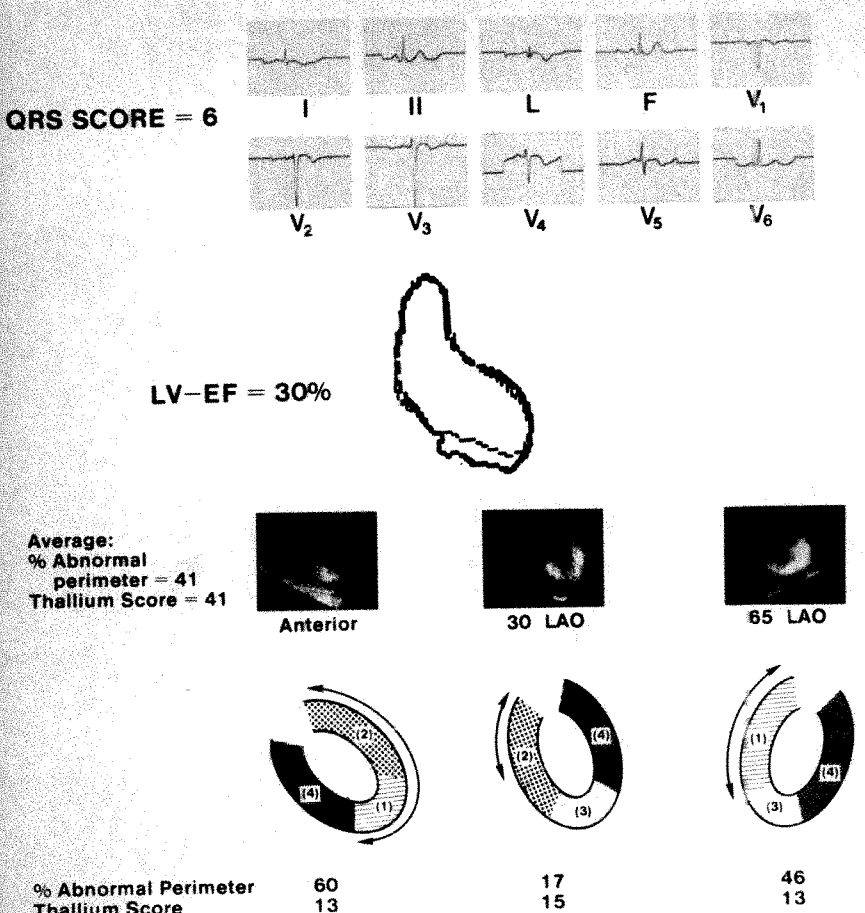

FIGURE 1. The QRS score, left ventricular (LV) radionuclide angiogram, and the thallium-201 images from a patient with acute anterior infarction. EF = ejection fraction; LAO = left anterior oblique projection.

the remaining segments by 2, yielding a score of 20 in each projection for a total score of 60 in 3 projections (Fig. 1). However, the results were not different even when a score of 4 was used for each segment. Therefore, a score of 40 would indicate that only two thirds of the left ventricle has normal uptake. Interpretations of the electrocardiogram, radionuclide angiograms, and thallium images were made independently without knowledge of the other results.

The inter- and intraobserver variability in measuring the left ventricular ejection fraction was 2.2 ± 1.5%[14] and the interobserver variability in measuring the thallium defects was 4 ± 4%; the maximal difference was 14% in a patient with large defects whereas the intraobserver variability in measuring the thallium defects was 3 ± 3%.[18,19] The intraobserver variability in measuring the QRS score was 2 ± 2% with a maximal difference of 5%.

Statistical analysis was performed using Student's *t* test or analysis of variance when appropriate. Values were expressed as the mean ± standard deviation (SD) when indicated. A probability (p) value less than 0.05 was considered to represent a statistically significant difference. Correlation between the variables was assessed with linear regression analysis.

Acute myocardial infarction: Of the 29 patients with acute infarction, the infarction was transmural (Q-wave infarction) in 20 patients: anterior in 9, inferior in 6, and both anterior and inferior in 5. The remaining 9 patients had non–Q-wave infarctions (nontransmural or subendocardial). There were 23 men and 6 women with an age range of 36 to 86 years (mean 61.2).

QRS scoring: Seven of the 29 patients (24%) had a QRS score of 2 or less. All 7 patients had non–Q-wave infarctions. In the remaining patients the QRS score varied between 3 and 18. Patients with transmural infarctions had higher scores than patients with non–Q-wave infarctions (8.3 ± 3.8 versus 1.6 ± 1.2, $p < 0.001$).

Left ventricular ejection fraction: The ejection fraction was ≥40% in 10 patients and <40% in the remaining 18 patients. The ejection fraction was significantly different in patients with transmural infarction and in patients with non–Q-wave infarction (28.7 ± 12.7% versus 45 ± 9.8%, $p < 0.001$).

Myocardial thallium-201 scintigraphy: Resting myocardial thallium-201 scintigrams were obtained 10 to 14 days after acute infarction in 22 patients. Twenty of the 22 patients (91%) had abnormal scans. There was a good correlation between the 2 methods used in this study in assessing perfusion defects, that is, perimetry versus scoring ($r = 0.91$, $y = 129.7 - 2.18x$) ($p < 0.001$) (Fig. 2). However, both sets of data (score and perimeter) were derived from the same image data and therefore such agreement is not unexpected. Validation of any method should be made by comparison with an independent, different method such as postmortem size of the infarction. However, such data were not available to us because none of the patients died during the study period.

Correlation between QRS score and left ventricular ejection fraction: There was an inverse correlation between ejection fraction and QRS score in the 28 patients with acute infarction in whom both studies were available ($r = -0.61$, y

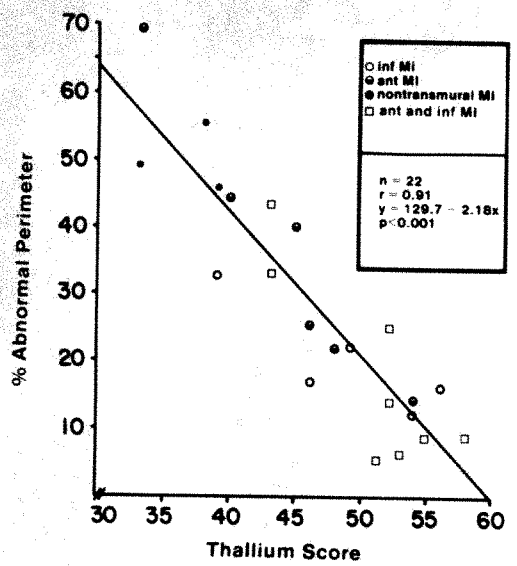

FIGURE 2. Comparison between thallium score and thallium percentage (abnormal perimeter) in 22 patients with acute myocardial infarction (MI). Ant = anterior; inf = inferior.

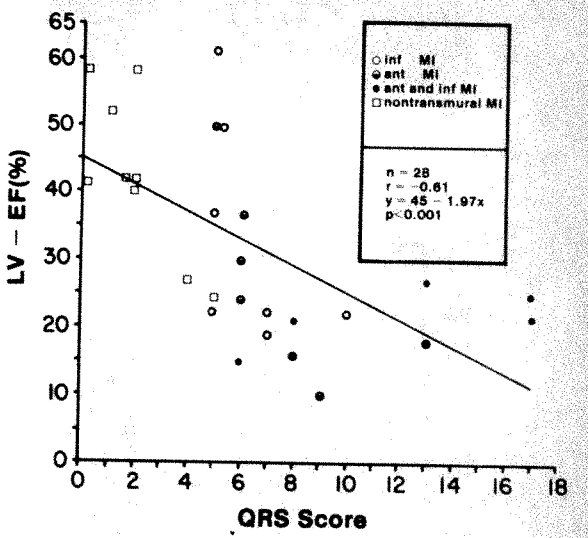

FIGURE 3. Comparison between QRS score and left ventricular ejection fraction (LV-EF) in 28 patients with acute infarction. Abbreviations as in Figure 2.

= 45 − 1.97x, p <0.001) (Fig. 3). All 7 patients with a QRS score ≤2 had an ejection fraction ≥40%. However, only 3 of the remaining 21 patients (14%) with a QRS score >2 had an ejection fraction ≥40% (p <0.01). In general, the higher the score, the lower the ejection fraction. Patients with a QRS score ≥10 had an ejection fraction of 30% or less.

Correlation between thallium-201 scintigrams and left ventricular function: As mentioned earlier, there was good agreement between the perimetric and scoring systems for evaluation of thallium scintigrams. We found a fair correlation between the size of the defect and the left ventricular ejection fraction (r = −0.71, y = 51.3 − 0.57x, p <0.001 by perimetry; and r = 0.70, y = 1.34x − 27.4, p <0.001 by thallium score)

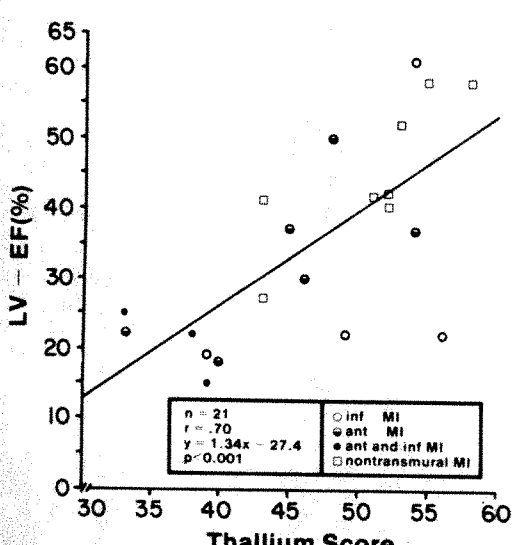

FIGURE 4. Comparison between the thallium score and left ventricular ejection fraction (LV-EF) in 21 patients with acute myocardial infarction. Abbreviations as in Figure 2.

(Fig. 4). Patients with small defects had higher ejection fractions than patients with larger defects. All 6 patients with a thallium score ≤40 had an ejection fraction ≤25%, whereas only 2 of 15 patients (13%) with a thallium score >40% had an ejection fraction <25% (p <0.01). Few exceptions were noted: 1 patient with a thallium score of 56 had an ejection fraction of 22%, and another patient with a score of 49 had an ejection fraction of 22%. The QRS score of the first patient was 5, also inappropriate for the level of ejection fraction, whereas the QRS score of the second patient was 10, appropriate for the corresponding ejection fraction of 22%. Apart from these exceptions, the higher the thallium score, the higher the ejection fraction in these patients.

Correlation between thallium score and QRS score: The correlation between the QRS score and the thallium score in patients with acute infarction (Fig. 5) was good (r = −0.65, y = 25.3 − 0.42x, p <0.001).

Patients with chronic myocardial infarction: Fifteen of the 43 patients had chronic anterior transmural infarction, 15 had chronic inferior transmural infarction, 2 had both anterior and inferior infarction, and 9 had non–Q-wave infarction. Two patients had bundle branch block and were excluded from QRS scoring. There were 37 men and 6 women, aged 35 to 69 years (mean 50.1). The left ventricular ejection fraction was measured in all 43 patients by first-pass radionuclide angiography. Although there was a statistically significant correlation between the QRS score and the left ventricular ejection fraction (Fig. 6), a wide scatter of ejection fractions was noted for a given QRS score. For example, for a score of 3, the ejection fraction ranged between 31 and 70%. The scatter was noted even at high QRS scores. Although 7 of 9 patients (77%) with a QRS score of 2 or less had a left ventricular ejection fraction >40%, 15 of 32 patients (47%) with a QRS score >2 also had an ejection fraction >40% (p not significant).

As indicated, 16 of these patients subsequently underwent coronary artery bypass. Resting thallium-201 scintigrams were available in 15 of the 16 patients preoperatively. Furthermore, 14 of these 15 patients had resting thallium scans 10 to 14 days postoperatively as well. The group of patients that underwent

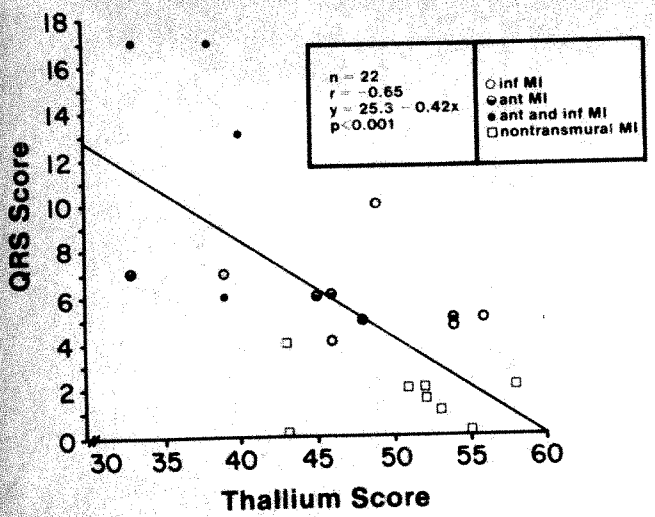

FIGURE 5. Comparison between QRS score and thallium score in 22 patients with acute myocardial infarction. Abbreviations as in Figure 2.

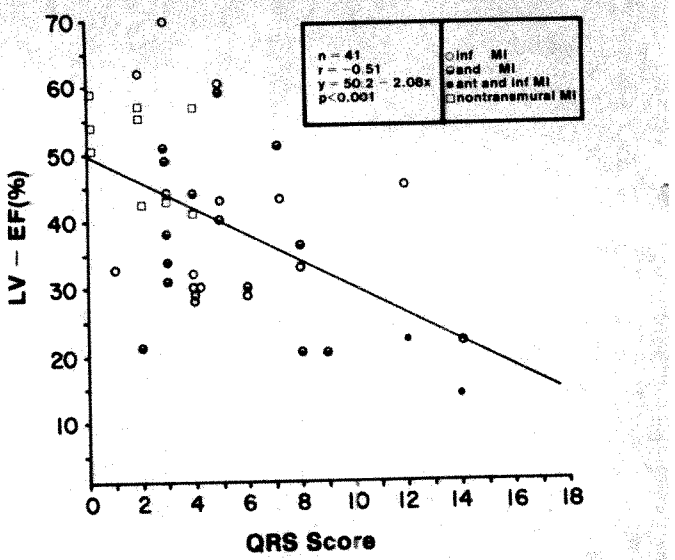

FIGURE 6. Comparison between QRS score and left ventricular ejection fraction (LV-EF) in 41 patients with chronic myocardial infarction. Abbreviations as in Figure 2.

surgery consisted of 14 men and 2 women, aged 41 to 69 years. Eight of the 16 patients had transmural inferior infarctions, 3 had transmural anterior infarctions, 1 had both anterior and inferior infarction, 2 had non–Q-wave infarction, and 2 had bundle branch block. The ejection fraction measured in 15 patients increased from 34 ± 8% preoperatively to 38 ± 12% postoperatively ($0.05 < p < 0.10$) and in the 14 patients who had both pre- and postoperative resting thallium scans, the thallium score improved from 40.7 ± 8.5 to 45.9 ± 9.0 ($p < 0.05$).

There was a fair correlation between the thallium score and the ejection fraction preoperatively in the 15 patients ($r = 0.61$, $y = 12.0 + 0.52x$) ($p < 0.02$) as well as between the postoperative ejection fraction and the postoperative thallium score in the 14 patients ($r = 0.75$, $y = -6.6 + 0.98x$, $p < 0.01$) (Fig. 7). The correlation between QRS score and ejection fraction was poor both pre- and postoperatively (p not significant). Similarly, there was a poor correlation between the QRS score and the thallium score both pre- and postoperatively (p not significant). Therefore, in these patients the QRS score had limited value in predicting left ventricular ejection fraction.

Discussion

The results of this study show that in patients with acute infarction, the QRS scoring system of Wagner et al[13] is reliable in predicting left ventricular function. Our study, therefore, confirms the conclusion of Palmeri et al,[11] although our correlation was lower than that reported by these investigators ($r = -0.61$ versus -0.88). It is worth emphasizing that the QRS scoring system cannot be used in patients with conduction defects, but can be used whether the myocardial infarction is transmural or nontransmural (non–Q-wave infarction). Although we studied a small group of patients with acute infarction, nevertheless these patients had a wide range of left ventricular function, QRS scores, and thallium scores and therefore these observations are likely to represent findings occurring more generally in other patients with acute infarction. Although a trend was observed in the correlation between the ejection fraction and the QRS score in patients with chronic myocardial infarction, the correlation was marginal ($r = -0.51$).

More important, careful analysis of Figures 3 and 6 shows that for any given score the ejection fraction varied widely in patients with chronic infarction but not in patients with acute infarction. These results are similar in some respects to those of Palmeri et al[11] but also show some differences. First, these investigators followed the same cohort of patients with acute infarction over 2 years. However, we studied entirely different groups of patients, 1 with acute infarction and 1 with

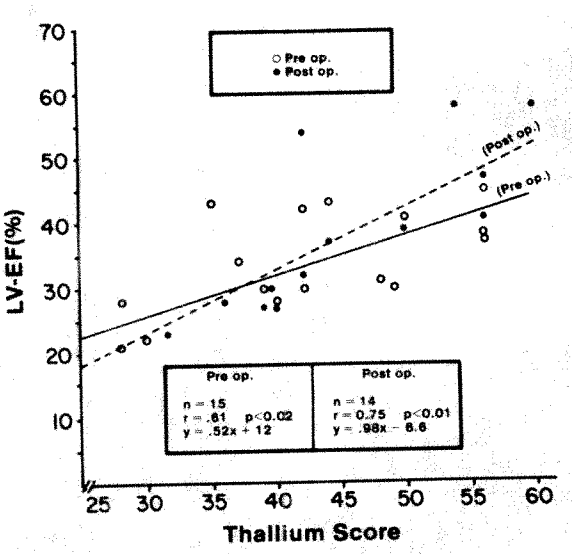

FIGURE 7. Comparison between thallium score and left ventricular ejection fraction (LV-EF) before and after coronary artery bypass surgery. Postop. = postoperative; precp. = preoperative.

chronic infarction. This difference in method is related to the design of the study—prospective in the case of Palmeri et al[11] and retrospective in our study. Second, even in the study of Palmeri et al,[11] the correlation between the QRS score and the ejection fraction was lower at 1 year than the correlation 2 weeks after acute infarction.

The exact reasons for the poorer correlation in patients with chronic infarction in both studies are not exactly known, but certain mechanisms can be postulated: for example, the disappearance of Q waves, a compensatory increase in the end-diastolic volume, and the effects of medications that may alter preload, afterload, and contractility. Finally, the presence or absence of myocardial ischemia at rest cannot be discounted.

It appears that the common denominator between the QRS score and the left ventricular ejection fraction is the amount of infarcted myocardium. A significant correlation between the extent of myocardial fibrosis and left ventricular function has been shown.[21] The extent of thallium defect has been shown to correlate with pathologically determined infarct size and with the contrast angiographic extent of asynergy.[22,23] We studied the extent of the infarcted myocardium in patients with acute infarction by means of thallium-201 scintigraphy at rest, and in fact found a fair correlation between the size of the perfusion defect, the ejection fraction, and the QRS score (Fig. 3 and 4). We also found that in patients with chronic infarction, the correlation between the size of the defect and the ejection fraction was still fair, but again we found a poor correlation between the QRS score and the size of the thallium defect in patients with chronic infarction.

In addition to fibrosis, resting thallium defects may represent chronic ischemia (or hypoperfusion). These perfusion abnormalities may be responsible for the segmental left ventricular wall-motion abnormalities seen in patients with chronic coronary artery disease in the absence of infarction: they may also explain the reversibility of these wall-motion abnormalities with nitroglycerin.[24] This assumption needs further study.

In the subgroup of patients with chronic infarction who underwent revascularization, the postoperative correlation between the ejection fraction and the size of the thallium defect was still fair (Fig. 7). However, as in the preoperative study, the correlation between the QRS score and the thallium score, or between the QRS score and the ejection fraction was poor. These results suggest that factors inherent in the QRS scoring system may be responsible for the poor correlation between the ejection fraction and the QRS score in patients with chronic infarction.

Our method for assessing the defect size seen on thallium scans is simple and may be performed in any laboratory. Moreover, the good correlation between a thallium scoring system and the perimetric method used in this study indicates that the scoring system may be preferred because of its simplicity. As noted earlier, the correlation between the 2 methods is not unexpected because both sets of data were derived from the same images. The ultimate validation of either method has to be made by a comparison with postmortem infarct size and probably with the contrast angiographic extent of asynergy as determined by other investigators.[22,23] However, neither postmortem nor contrast angiographic data were available in our patients. Even the defect size in the thallium scans did not correlate perfectly with the left ventricular ejection fraction ($r = 0.70$). There may be several related factors. First, some defects seen in the resting scans may represent ischemia (hypoperfusion) rather than scarring. Although it is our practice to obtain 4-hour delayed images after the initial resting images, the size of the defect as reported in this study represents the total defect size of both infarcted and possibly ischemic myocardium.

Second, the left ventricular ejection fraction may have been affected by factors that modify the preload, afterload, and contractility.[25] Third, as demonstrated in 2 patients with a small thallium defect in this study, the ejection fraction was disproportionately low compared with the size of the defect. In these patients an independent cardiomyopathic process may have been responsible for lowering the ejection fraction. It is well known that patients with nonischemic cardiomyopathy may have very low ejection fractions despite the presence of normal or near-normal left ventricular function[26] (Fig. 4 and 7).

Clinical implications: This study confirms a previous report that the QRS scoring system is of value in predicting left ventricular function in patients with acute infarction. With practice, the QRS score may be obtained in less than 1 minute. Therefore, this simple, inexpensive, and routinely available test is useful under these circumstances. However, caution should be applied in using the QRS scoring system in patients with old infarction. Although the QRS scoring system does not provide absolute measurements of the ejection fraction, it may help classify the patients into groups with normal or near-normal left ventricular function and mild to moderate left ventricular dysfunction. Furthermore, the size of infarction as assessed by thallium-201 correlated with left ventricular function in patients with acute or chronic infarction as well as in patients after revascularization surgery.

Finally, we should not be misled by a good p value, but should look rather at the spread of the data points. The ultimate purpose of these methods is to apply them clinically. It is clear that in individual patients, we cannot reliably predict left ventricular ejection fraction. The closest thing we can probably do is categorize the patients into those with low, moderate, and normal ejection fraction. This categorization could be done by using the QRS scoring system in acute infarction and by thallium imaging in patients with acute or chronic infarction.

Current Incidence of Postmyocardial Infarction (Dressler's) Syndrome

EDGAR LICHSTEIN, MD, EDWARD ARSURA, MD, GERALD HOLLANDER, MD, ALVIN GREENGART, MD, and MICHAEL SANDERS, MD

This study examines the current incidence of postmyocardial infarction (Dressler's) syndrome. During 1980, 282 patients with documented myocardial infarction were admitted to our coronary care unit. Early postmyocardial infarction pericarditis was present in 18 patients (6.4%). Six of these patients received steroids and the remainder were treated with salicylates or other anti-inflammatory drugs. Anticoagulation was used in 149 patients (53%) during hospitalization. One hundred forty-four (51%) were receiving heparin and 133 (47%) received no anticoagulation. Information on the patient's status at 6 months was available in 229 patients who were discharged alive. Sixteen patients had died within 6 months after discharge and 4 patients were lost to follow-up study. There were no documented cases of Dressler's syndrome.

It is concluded that Dressler's syndrome has decreased in incidence and perhaps disappeared. This decrease is most likely related to decreased use of oral anticoagulants and to more aggressive treatment of postmyocardial infarction pericarditis.

The postmyocardial infarction syndrome (Dressler's) was described at our medical center in 1956.[1] Clinical features of this syndrome include fever, chest pain, pericarditis, pleurisy, and pneumonitis and a tendency to recurrence.[2-4] Dressler[2] estimated that this complication occurred in 3 to 4% of recent myocardial infarctions. Our experience indicates that this syndrome has significantly decreased in frequency and perhaps no longer occurs. This study reports the current incidence of this complication and examines the possible explanations for this change.

Methods

The study population consisted of patients with a well-documented acute myocardial infarction who were admitted to our coronary care unit during 1980. The presence of acute myocardial infarction was established if the patient had electrocardiographic abnormalities consistent with the Minnesota code for acute myocardial infarction, in addition to typical symptoms of acute myocardial infarction and elevated serum enzyme levels. This electrocardiographic classification of acute myocardial infarction includes nontransmural as well as transmural myocardial infarction. Elevated levels of 2 or more enzymes including serum glutamic oxalacetic transaminase, lactic dehydrogenase, and creatinine phosphokinase to at least twice the upper limit of normal for our laboratory within 72 hours of the onset of symptoms were required for diagnosis.

All patients received routine coronary care which included auscultation of the heart at least twice daily. A diagnosis of postmyocardial infarction pericarditis was established when the patient noted pleuropericardial pain and a definite pericardial friction rub was audible. We did not include patients with a friction rub alone in order to avoid false diagnoses caused by chest wall motion against the stethoscope. Information on anticoagulation during hospitalization and all other clinical data were prospectively gathered on a computerized data form which is completed for every patient with acute myocardial infarction.

Information concerning the presence or absence of Dressler's syndrome was obtained by questionnaires that were completed by the patient's referring physician. This information was used, in addition to the prospectively gathered information obtained during the patient's hospitalization, to determine the precise incidence of complications from the time of admission to 6 months after myocardial infarction. The questionnaire requested information on the patient's status, therapy including anticoagulation, and the presence or absence of Dressler's syndrome. If a diagnosis of Dressler's syndrome was made, the physician was asked to indicate the presence or absence of specific abnormalities which included temperature elevation, pleuropericardial pain, pleuropericardial rub, elevated eosinophilic sedimentation rate (>20 mm/h), elevated white blood cell count (>10,000/mm^3), pneumonitis, and x-ray evidence of cardiomegaly.

Address for Reprints: Edgar Lichstein, MD, Division of Cardiology, Maimonides Medical Center, 4802 Tenth Avenue, Brooklyn, New York 11219.

Using Dressler's original criteria,[2] Dressler's syndrome was suspected when a febrile period after myocardial infarction lasted longer than 1 week and was accompanied by pleuropericardial pain, or when fever and chest pain recurred. The diagnosis was confirmed when a pericardial rub was audible for 3 days or longer or when it appeared late in the course of the illness.

Results

From January 1, 1980 through December 31, 1980, 282 patients with documented myocardial infarction were admitted to our coronary care unit.

Early postmyocardial infarction pericarditis was seen in 18 patients (6.4%) during the initial hospitalization. Twelve of these patients had anterior and 6 had inferior wall myocardial infarction. In each case a pericardial rub was heard on the second or third postmyocardial infarction day, lasted only 1 or 2 days, and did not recur. No evidence of pneumonitis or significant pericardial effusion was noted on chest x-ray. Six of these patients had echocardiograms that also failed to show significant pericardial effusion. Six of the patients received parenteral steroids for the treatment of pericarditis, while the remainder were treated with salicylates or other anti-inflammatory agents. Five patients died during hospitalization.

Questionnaires were returned on 229 patients who were discharged alive from our coronary care unit after myocardial infarction. Sixteen questionnaires indicated that the patient had died within 6 months of discharge and 4 patients were lost to follow-up study. Dressler's syndrome was thought to be present in only 2 patients by the referring physician. We did not believe that this diagnosis was substantiated in either case. One patient had pleuropericardial pain and a temperature elevation after insertion of a temporary pacemaker. A pericardial rub was never documented and the temperature promptly returned to normal after antibiotic therapy. The second patient also had no documentation of a pericardial rub or temperature elevation.

Anticoagulant therapy was used in 149 patients (53%) during the initial hospitalization. One hundred forty-four patients (51%) were receiving heparin and only 5 patients (2%) received coumadin; 133 patients (47%) received no anticoagulants.

Discussion

To study the incidence of Dressler's syndrome, it is necessary to define it precisely and to carefully distinguish it from the more common early postmyocardial infarction pericarditis.

Dressler[2] estimated that this complication occurred in 3 to 4% of myocardial infarctions, whereas Broch and Ofstad[4] noted only a 1% incidence. The clinical features of Dressler's syndrome include fever, pleuropericardial chest pain, evidence of pneumonitis, and a tendency to recur.[2,5] Because many of these features are seen with early postmyocardial infarction pericarditis, it is important to look for features that are specific for Dressler's syndrome. Dressler[2] noted that the rub occurred late in the syndrome he described. Most rubs occurred between the 2nd and 11th weeks and persisted 3 days to many weeks. The specificity of a late occurring rub has recently been questioned. Kossowsky et al[6] described 5 patients with Dressler's syndrome within 1 week after myocardial infarction. They based their diagnosis on the finding of pericardial fluid which they believe does not occur with early postmyocardial infarction pericarditis. Because the time of onset of pericarditis is not specific, the persistence of pericarditis, recurrence, and presence of pericardial effusion are probably the best indicators of Dressler's syndrome. We were unable to find even 1 patient with characteristics of this type of persistent and recurrent pericarditis. In addition, none of our patients with early postmyocardial infarction pericarditis had evidence of significant pericardial effusion judged by either echocardiogram or conventional chest x-ray.

The incidence of early postmyocardial infarction pericarditis varies from 6.8 to 16%[7–11] and depends largely on the frequency of examination. This type of pericarditis usually occurs on the second to fourth postmyocardial infarction day and lasts only 1 or 2 days. There is frequently a slight temperature elevation which is usually associated with myocardial necrosis. Pneumonitis does not commonly occur and significant pericardial effusion is not found.[5,9] Our incidence of 6.4% and the clinical picture we observed are consistent with this description.

Kossowsky et al[12] believe that the separation of pericarditis after myocardial infarction into 2 varieties is "arbitrary and artificial." They feel that patients with Dressler's syndrome have all had early postmyocardial infarction pericarditis and are simply a subgroup in whom prolonged and severe pericarditis develops. Other investigators[7,8,11] have described a series of patients with early postmyocardial infarction pericarditis, in a small proportion of whom Dressler's syndrome later developed. We believe that 2 definite forms of pericarditis did previously exist.

Various causes of Dressler's syndrome have been proposed and must be considered when looking to explain its decreased incidence. Dressler et al[13] believed that inflammatory complications of myocardial infarction such as pericarditis were allergic in nature and represented a hypersensitivity reaction to autoantigens resulting from myocardial necrosis. Heart muscle antibodies have been found in patients after myocardial infarction.[14] Some studies report this more commonly in patients with Dressler's syndrome,[15] leading to the theory that myocardial infarction releases cardiac substances that behave as autoantigens and cause the clinical syndrome.[16] Liem et al[17] found antibodies to heart muscle in 12% of patients with myocardial infarction but none had evidence of Dressler's syndrome. They conclude that heart muscle antibody cannot be considered specific for the development of Dressler's syndrome. Kossowsky et al[12] also believe that there is no evidence for an autoimmune mechanism. Burch and Colcolough[18] suggest a viral cause, with the trauma of myocardial infarction reactivating latent or dormant viral infection.

Dressler[2] postulated that anticoagulant therapy might play a role in etiology by causing leakage of blood into the serous cavities which would cause signs of pericarditis. He also noted that 75% of his patients were receiving anticoagulants and 25% were not. Anticoagulation at the time of Dressler's original report consisted of oral bishydroxycoumarin which was usually started with a high loading dose. The difference in anticoagulant use and incidence is an important finding in our study. Although 53% of our patients were being given anticoagulants, heparin was used almost entirely, which is much easier to control and less likely to cause significant pericardial bleeding. An extensive area of pericardial irritation, therefore, is less likely to occur.

Difference in observer awareness is a possible explanation of our incidence of Dressler's syndrome. We believe that this is unlikely, because Dressler's syndrome was originally described at this Medical Center and our level of awareness of this syndrome is high. Davidson et al[19] stated that the diagnosis should present little difficulty provided the physician is aware of its existence.

Therapy of early postmyocardial infarction pericarditis may affect the incidence of Dressler's syndrome. Several investigators[7,8,11] noted that their patients with Dressler's syndrome also had early postmyocardial infarction pericarditis. Dressler's syndrome may be merely a continuing pericarditis that occurs in a small subgroup of patients. Six of our 16 patients with early pericarditis were treated with steroids, whereas the remainder were aggressively treated with salicylates or other anti-inflammatory drugs.

We conclude that Dressler's syndrome has decreased in incidence and perhaps disappeared. This decrease does not appear to be explained by decreased physician awareness or changes in coronary care unit procedure. We suggest that it most likely related to decreased use of oral anticoagulants and to more aggressive treatment of early postmyocardial infarction pericarditis.

Spontaneous Changes in Thallium-201 Myocardial Perfusion Imaging After Myocardial Infarction

ANDREW J. BUDA, MD, JAMES D. DUBBIN, MD, IAN L. MACDONALD, MD, HANS D. STRAUSS, MD, SALLY A. ORR, RN, and HARRY MEINDOK, MD

To examine regional myocardial perfusion after myocardial infarction, 26 patients underwent exercise electrocardiographic testing with thallium-201 myocardial perfusion imaging 3 weeks and 3 months after infarction. At 3 weeks, 9 of 26 patients (35%) had myocardial ischemia by exercise electrocardiographic testing, whereas 18 of 26 (69%) had ischemia by thallium-201 imaging. The thallium-201 scintigrams were scored by dividing each image, in 3 views, into 5 segments, using a 5-point scoring scheme. The exercise thallium-201 score was 44.3 ± 1.2 and increased to 47.3 ± 1.2 in the redistribution study ($p < 0.001$). Three months after infarction, although there was a significantly greater rate-pressure product which would predict a larger ischemic defect and a decrease in the stress thallium-201 score, the stress score was improved (48.3 ± 1.1, $p < 0.001$). The redistribution score was similar, that is, 48.9 ± 1.0. The improvement in thallium-201 myocardial perfusion was associated with a loss of stress-induced ischemia in 8 patients (30%). These results indicate that spontaneous improvements in thallium-201 myocardial perfusion imaging may occur after myocardial infarction.

The first few weeks after myocardial infarction are characterized by an improvement in exercise capacity and myocardial oxygen demands.[1-3] Various explanations, including a "training effect" with peripheral adaptation and neurally mediated reflex cardiac changes, have been suggested to explain this phenomenon.[3] However, some investigators speculate that there may be an improvement in myocardial oxygen supply,[1,4] possibly through collateral channels that are commonly seen after infarction. In this respect, Borer et al[4] postulated that improved myocardial perfusion through collateral formation may explain improvement in left ventricular function and reserve seen in some patients within the first year after infarction.

Thallium scintigraphy in the early postinfarction period accurately predicts multivessel disease and jeopardized myocardium.[5] However, serial studies of myocardial blood flow in the weeks after myocardial infarction have not previously been performed. To further explore changes in myocardial perfusion in the early convalescent phase after myocardial infarction, we studied 26 patients serially 3 weeks and 3 months after infarction with thallium-201 myocardial perfusion imaging.

Methods

Twenty-six patients with acute myocardial infarction were evaluated prospectively. All patients gave written informed consent on entry into the study and before each exercise testing session. There were 24 men and 2 women aged 35 to 68 years (mean 55 ± 8.8). Six patients had a previously documented myocardial infarction. All patients fulfilled the following diagnostic criteria for acute infarction: an evolutionary serum enzyme pattern consistent with myocardial necrosis including an elevation in the creatine kinase MB isoenzyme fraction, and at least 1 of the following 2 criteria: retrosternal chest pain consistent with myocardial ischemia lasting at least 30 minutes, or electrocardiographic changes. The diagnostic electrocardiographic changes of transmural myocardial infarction included S-T segment elevation, T-wave inversion, and development of Q waves of at least 40 ms in duration and 25% or greater than the R-wave amplitude in the same lead. The electrocardiographic criteria for nontransmural myocardial infarction consisted of S-T segment depression of

T-wave inversion persisting at least 24 hours without the development of pathologic Q waves.

With the foregoing electrocardiographic criteria for location and type of infarction, 5 patients (20%) had an anterior transmural infarction, 13 patients (50%) an inferior transmural infarction, and 8 patients (30%) nontransmural infarction.

Patients excluded from this study included (1) those older than 69 years; (2) those with postinfarction angina at rest or of a changing nature; (3) those with hemodynamically significant valvular heart disease suspected on clinical and noninvasive examination; (4) those with uncontrolled hypertension (blood pressure greater than 170/100 mm Hg) despite medical therapy; (5) those with complications related to myocardial infarction such as clinical congestive heart failure despite medical therapy or pulmonary embolism; and (6) those with an exercise-limiting musculoskeletal abnormality.

Each patient was classified according to the Killip and Kimball classification[6] and to the coronary prognostic index of Norris et al.[7] All patients underwent enzymatic estimation of infarct size as determined by serial total creatine kinase (CK) curves. Blood samples were obtained on admission and every 4 hours during the first 72 hours. Total CK was assayed spectrophotometrically by the method of Rosalki.[8] The infarct size was estimated by analysis of serial CK determinations as described by Shell et al.[9] Infarct size was corrected for body surface area and expressed as an infarct size index (ISI) in CK-g-Eq/m^2.

Three-week assessment: Approximately 3 weeks (24.4 ± 3.9 days) after myocardial infarction, each patient was interviewed and examined by a physician. The patients then underwent symptom- or sign-limited treadmill exercise testing using a modified Naughton protocol. The end points of exercise were: (1) development of symptoms that increased, leading directly to termination of effort, that is, chest pain, dyspnea, fatigue, leg cramps, or dizziness; (2) development of signs such as decrease in systolic blood pressure of at least 10 mm Hg below the peak value obtained at a previous stage of exercise or the appearance of ventricular tachycardia (3 successive ventricular premature beats). At peak exercise, 1.5 mCi of thallium-201 (New England Nuclear, North Billerica, Massachusetts) was injected intravenously and exercise was continued, when possible, for an additional 60 seconds. Twelve-lead electrocardiograms and blood pressure measurements were recorded at rest, before exercise testing, and at the end of each 3-minute stage of exercise and at 1, 2, 3, 5, and 7 minutes after exercise (or until the electrocardiogram returned to the preexercise state).

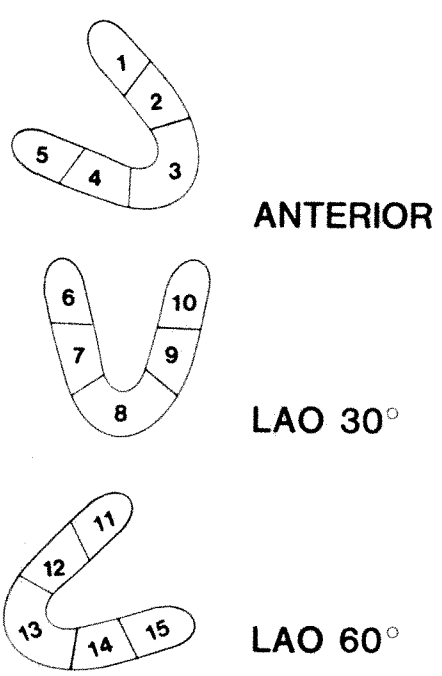

FIGURE 1. Diagram illustrating the thallium study scoring system. Each of the 3 projections (anterior, LAO 30°, and LAO 60°) was divided into 5 segments, resulting in 15 segments (as numbered) in each study. Each segment was scored from 0 to 4, as follows: 0 = severely abnormal, 1 = moderately abnormal, 2 = mildly but definitely abnormal, 3 = equivocally abnormal, and 4 = normal activity. LAO = left anterior oblique.

After the recovery period, myocardial imaging of thallium-201 was recorded using a scintillation camera (Searle Pho/Gamma IV, Des Plaines, Illinois) set for 80 keV with a low energy, all-purpose parallel hole collimator. Data collection was begun in all cases within 10 minutes of radioactive tracer injection. Data were collected in each of the 3 projections (anterior, 30° left anterior oblique, and 60° left anterior oblique). Between 250,000 and 300,000 counts were collected per projection. All images were collected using a Polaroid® photographic record obtained directly from the camera's cathode ray display. In addition, the data were collected and viewed on a dedicated nuclear medicine computer (A^2, Medical Data Systems, Ann Arbor, Michigan). Thallium imaging and data collection were repeated 4 hours after exercise, as aforementioned, to assess redistribution of isotope.[10]

Exercise and postexercise electrocardiograms were analyzed for a positive or negative response. A positive response was defined as either S-T segment horizontal or downsloping depression of 1.0 mm 0.08 second after the J point or 1.0 mm S-T segment elevation above baseline electrocardiogram for the corresponding leads.

Thallium-201 images were independently assessed semiquantitatively by 2 experienced interpreters unaware of the patient's history and electrocardiographic exercise test results. Each projection was divided into 5 regions of interest and perfusion in each region scored from 4 (normal) to 0 (severely abnormal) (Fig. 1). In cases of disagreement, a consensus score was determined. The final score of each projection was tabulated and a total score, using all 3 projections, was derived. A normal study score was 60. The immediate postexercise images were compared with the 4-hour postexercise images and the perfusion in each region was scored as just described. The thallium study was defined as being representative of an ischemic response if a defect present on the immediate postexercise study became smaller or disappeared on the 4-hour postexercise (rest) study and the total score of the rest study was 2 or more points greater than the immediate postexercise study.

With this thallium scoring system the mean interobserver variability determined by having 2 observers independently score 71 scans was 1.2 ± 1.1 scoring points. In addition, this semiquantitative scoring system correlates well with a computer-derived scoring system.[11,12]

Three-month assessment: At approximately 3 months (mean 90.0 ± 4.7 days), each patient was reexamined, reinterviewed, and then subjected to a symptom- or sign-limited treadmill exercise test using the Bruce exercise protocol. Electrocardiographic recordings and thallium-201 injection with subsequent postexercise and rest studies were performed and analyzed as in the 3-week postmyocardial infarction studies.

Ant = anterior; Dig = Digoxin; E = exercise; ETT = exercise treadmill testing; Inf = inferior; ISI = infarct size index (CK-g-Eq/m^2); N = nitrates; 0 = no medications; Prop = propranolol; MI = myocardial infarction; NTM = nontransmural; R = redistribution; RPP = rate-pressure product (mm Hg/min $\times 10^3$); TM = transmural.

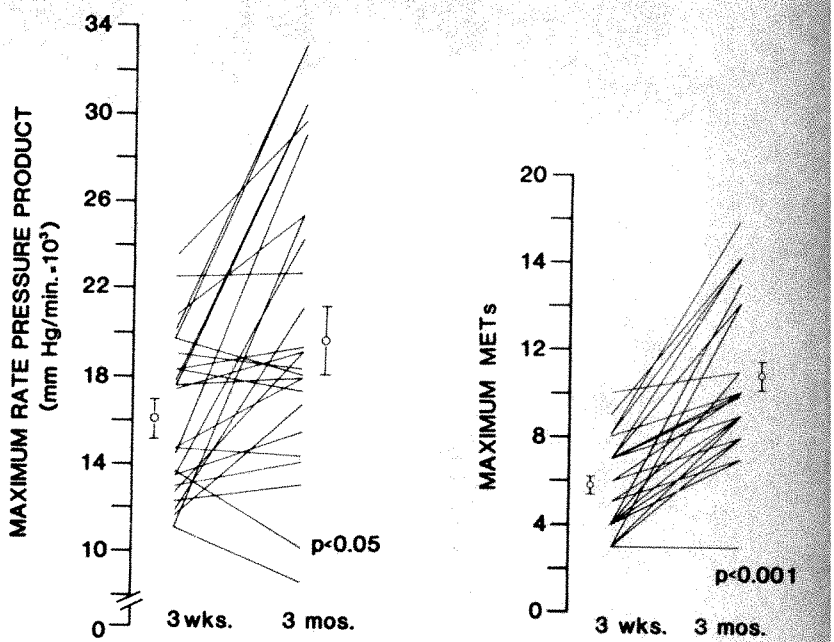

FIGURE 2. Both the maximal rate-pressure product and exercise work load for the entire study population increased significantly at 3 months compared with 3 weeks.

The thallium-201 studies obtained at 3 weeks were also compared with those at 3 months. As just described, semiquantitative assessment of perfusion alterations between corresponding sites of comparable projections at 3 weeks and 3 months was made immediately and after redistribution. Throughout the study, no attempt was made to standardize or influence medical therapy except to withhold the administration of any nitrates 90 minutes before each exercise test.

Analysis of data: Intragroup variables at 3 weeks and 3 months were compared using the paired t test. Intergroup variables at 3 weeks and 3 months were compared using the unpaired t test. Chi-square analyses and Fisher exact test were used to compare inter- and intragroup differences in the type and location of myocardial infarction and also to compare changes in ischemic response between those at 3 weeks and those at 3 months. All values given in the text are expressed as mean ± standard error of the mean.

Results

Individual patient data and results of exercise electrocardiographic and thallium testing are summarized in Table I. All patients had myocardial infarction and were categorized as Killip class I (22 patients) or Killip class II (4 patients). The mean Norris index for the group was 5.5 ± 0.4. The mean infarct size was 18.9 ± 2.6 CK-g-Eq/m^2. The patients were discharged from the hospital after 12.9 ± 0.9 days.

Three-week assessment: The study patients exercised to a mean work load of 5.9 ± 0.4 multiples of resting energy expenditure (METs), achieving a maximal rate-pressure product of 16.2 ± 0.7 mm Hg/min × 10^3 (Fig. 2).

During exercise, chest pain consistent with angina developed in 3 patients (12%), and 9 patients (35%) had positive electrocardiographic changes of myocardial ischemia. With thallium-201 scintigraphy, 18 patients (69%) had evidence of myocardial ischemia.

All patients demonstrated defects on redistribution rest thallium-201 studies compatible with myocardial infarction. All of the patients with myocardial ischemia on thallium-201 scintigraphy had evidence of ischemia on exercise studies in the peri-infarct areas. However, in addition, 8 patients (40%) with myocardial ischemia on thallium-201 scintigraphy also had evidence of ischemia on exercise studies, which occurred in a remote site in a separate vascular region from the rest defects. The exercise thallium-201 perfusion score was 44.3 ± 1.2 and increased in the redistribution rest study to 47.7 ± 1.2 ($p < 0.001$) (Fig. 3).

Medication at the time of the initial study included digoxin (7 patients), beta-blocking drugs (11 patients), and nitrate compounds (9 patients). Four of the patients taking beta-blocking drugs had been on this medication before their study infarction.

Three-month assessment: No coronary events were recognized between the 3 week and 3 month assessments. The study patients achieved a work load of 10.8 ± 0.8 METs, which was significantly greater than that of the 3 week assessment ($p < 0.001$). Similarly, a higher maximal rate-pressure product was achieved (20.0 ± 1.7 mm Hg/min ×10^3) ($p < 0.05$) (Fig. 2).

During exercise, 4 patients (15%) experienced angina. In 3 of these patients angina had developed at the 3-week exercise session. Myocardial ischemia was thought to be present on the basis of electrocardiographic evaluation in 13 patients (50%). Stress thallium-201 perfusion imaging demonstrated ischemia in 10 patients (38%), in all in an area adjacent to the infarction. In addition, 3 of these patients (15%) had evidence of remote ischemia. The stress thallium-201 score was significantly improved at 3 months (48.3 ± 1.1, $p < 0.001$) (Fig. 3 and 4). However, the redistribution thallium-201 score at 3 months, 48.9 ± 1.0, was not significantly

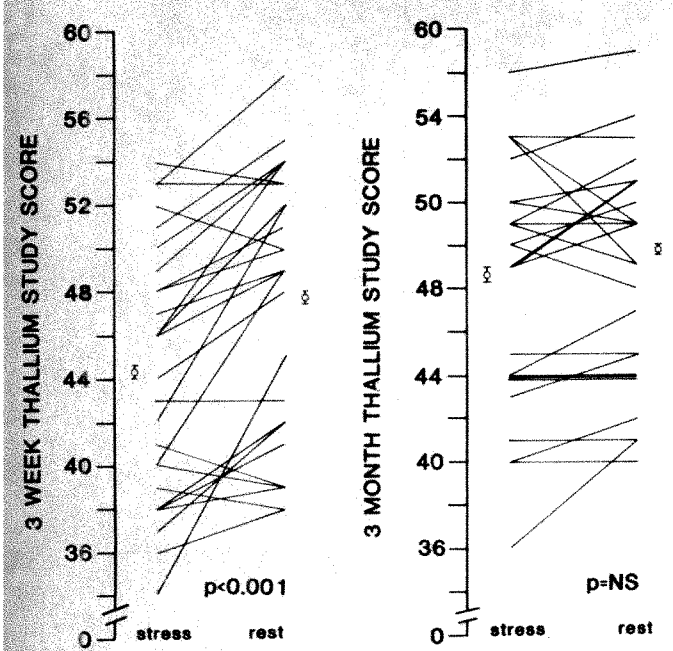

FIGURE 3. The thallium rest and stress study scores at both 3 weeks and 3 months for the entire study population are illustrated. There was a significant difference between the rest and stress scores at 3 weeks but not at 3 months.

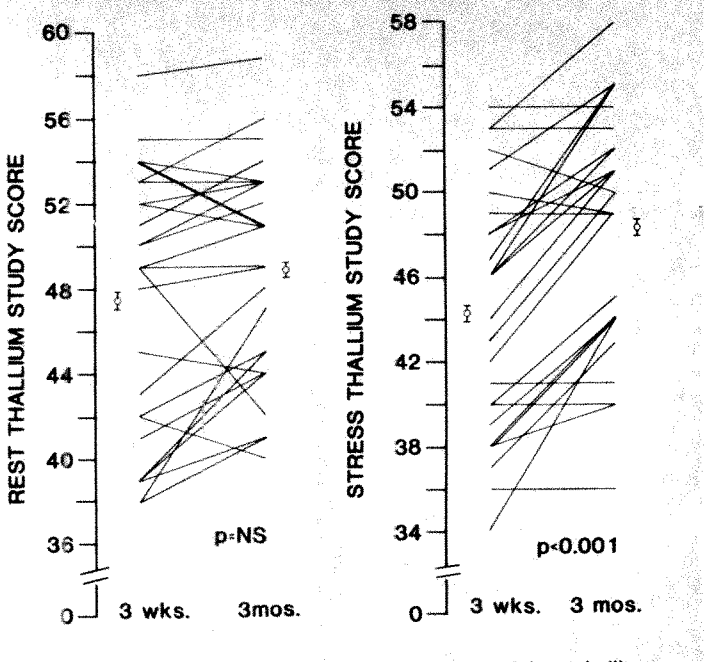

FIGURE 4. There was no signicant difference in the serial rest thallium study scores between 3 weeks and 3 months. However, a significant increase in the serial stress thallium study scores for the entire study group was seen.

changed compared with that at 3 weeks (Fig. 3 and 4). An example of improvement in the thallium-201 scintiscan is illustrated in Figure 5.

Few medication changes were made in the 3-week to 3-month interval. One patient had discontinuation of propranolol and 1 patient of nitrate therapy, whereas 2 other patients were started on nitrates.

Thallium perfusion changes: On the basis of changes in myocardial perfusion, 2 groups were identified: Group I consisted of 18 patients (69%) who demonstrated an improvement in thallium perfusion between 3 weeks and 3 months, and Group II included 8 patients (31%) who showed no such improvement.

No significant differences between the 2 groups were noted in terms of age; previous infarction; Killip and Norris indexes; type, location, and size of myocardial infarction; and medications at the time of study. Nine patients in Group I received beta-blocking drugs throughout the study as compared with 1 patient in Group II.

In Group I the exercise thallium-201 score was 43.2 ± 1.2 at 3 weeks and increased to 49.0 ± 1.3 ($p < 0.001$). An improvement in the redistribution thallium-201 study also occurred between that at 3 weeks and that at 3 months (from 46.7 ± 1.4 to 49.0 ± 1.3 [$p < 0.01$]). In Group II the exercise thallium score at 3 weeks was 46.8 ± 2.4 and was unchanged at 3 months (46.7 ± 2.2, p = NS). Similarly, no change occurred in the redistribution thallium-201 image between 3 weeks and 3 months (49.1 ± 2.4 to 48.6 ± 2.1 [p = NS]).

Group I patients had a significant increase in both the work load developed (5.7 ± 0.4 to 10.7 ± 0.9 METs [$p < 0.001$]) and the maximal rate-pressure product (15.3 ± 0.9 to 21.3 ± 1.9 mm Hg/min × 10^3 [$p < 0.001$]) from the 3-week to the 3-month exercise testing session. Group II patients also had a significant increase in the work load developed on the 3-month exercise test (6.5 ± 0.8 to 11.0 ± 1.3 METs [$p < 0.01$]). However, Group II patients did not have a significant increase in the maximal rate-pressure product between tests (18.0 ± 1.1 to 18.4 ± 2.6 mm Hg/min × 10^3).

Seven patients who demonstrated an ischemic response at 3 weeks but none at 3 months on thallium-201 imaging were taking beta-blocking medication. All of these patients were in Group I.

Discussion

Thallium-201 myocardial perfusion imaging is a technique to evaluate regional myocardial blood flow[13] that has proved useful in detecting, localizing, and sizing myocardial infarction and surrounding jeopardized ischemic myocardium.[14–17] Wackers et al[14] demon-

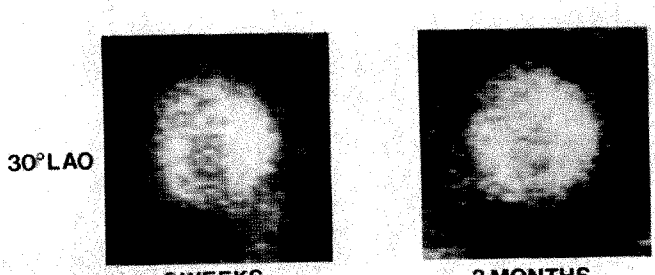

FIGURE 5. Serial thallium stress images of a Group I patient, illustrating improved perfusion in the inferoapical region at 3 months (**right**) compared with 3 weeks (**left**).

strated that thallium defects diminish in size in the first few hours and days after myocardial infarction. Regression of ischemia and possible formation of collaterals were suggested as possible explanations for this phenomenon. Our study was designed to further investigate myocardial perfusion in the convalescent phase of myocardial infarction and to document serial changes that occur in the first 12 weeks after infarction.

Our results indicate that myocardial perfusion assessed by thallium scintigraphy may improve between 3 weeks and 3 months after myocardial infarction, suggesting spontaneous improvement in regional myocardial flow in the weeks after infarction.

Thallium imaging is a highly reproducible technique for examining myocardial perfusion abnormalities.[18] In serial studies, increasing the exercise workload and rate-pressure product produces greater perfusion abnormalities in patients with coronary disease, thus increasing the sensitivity of the test.[18] By contrast, our study indicates an improvement in myocardial perfusion in 69% of our study patients at 3 months, despite significantly greater workloads and rate-pressure products. The fact that improved thallium-201 perfusion was demonstrated despite significantly greater rate-pressure products, and hence increased myocardial oxygen demands, underscores the improvement in regional myocardial blood flow in these patients.

This improved myocardial perfusion is best explained by some form of a revascularization process that occurs in the first few weeks after infarction. Collateral vessels modulate infarct size after coronary occlusion in dogs[19]; however, their role during infarction in man remains poorly understood. Angiographic studies show that collateral vessels occur commonly in the first year after infarction.[20,21] Moreover, Rigo et al[12] demonstrated that collateral vessels may account for normalization of the thallium scans and protection from stress-induced ischemia. Other investigators demonstrated improvement in myocardial perfusion after revascularization with coronary artery bypass grafting[22–25] or percutaneous transluminal coronary dilatation.[26] Thus, the improved regional myocardial perfusion that we observed is consistent with revascularization, presumably through collaterals or recanalization of vessels,[27] in the first few weeks after infarction.

Previous studies[28–30] have suggested that myocardial perfusion may improve in some patients after myocardial infarction. These investigators[28–30] noted normalization of thallium-201 scintigrams after myocardial infarction. Verani et al[30] demonstrated that periinfarction ischemia occurs commonly with chronic infarction and that other areas of prior necrosis apparently reestablish vascularity sufficient to afford total redistribution of thallium-201 on delayed postexercise imaging. However, none of these reports documented this improvement using serial thallium-201 myocardial perfusion studies.

When compared with stress electrocardiographic testing, thallium scintigraphy in our study was more sensitive in detecting ischemia at 3 weeks postmyocardial infarction. Ischemia, as assessed by thallium, was always contiguous to the area of infarction, but in 40% of patients additional remote ischemia in a separate vascular region suggested multivessel disease.[5] As a result of the improved perfusion between 3 weeks and 3 months, stress electrocardiography was equally as sensitive as thallium imaging in detecting ischemia at 3 months postinfarction. This spontaneous improvement in myocardial perfusion eliminated stress-induced residual ischemia in 30% of the study patients. Thus, the development of increased perfusion may have a protective effect against recurrent ischemic episodes.

Similar to previous reports,[1–3] exercise capacity and peak rate-pressure product in our patients improved in the interval between 3 weeks and 3 months postmyocardial infarction. Haskell and DeBusk[3] speculated that gradual waning of a reflex arising from dyskinetic myocardial segments or a "training effect" may be responsible for this improvement. However, Wohl et al[1] suggested that the improved rate-pressure product and exercise capacity could best be explained by an improvement in myocardial oxygen supply. Our data demonstrating improved myocardial perfusion support this suggestion.

Previous studies have shown that myocardial function can improve after myocardial infarction.[4,31,32] Recently Borer et al,[4] using radionuclide angiography, demonstrated spontaneous improvement in ventricular function within the 1st year after infarction in 17 of 40 patients who were a subgroup of patients with less damage and more viable myocardium and a resting ejection fraction greater than 40%. Borer et al[4] suggested that this improvement in ventricular function was related to a possible improvement in myocardial oxygen supply because of progressive development of collateral vessels. Our data demonstrating a spontaneous improvement in myocardial perfusion after infarction supports this hypothesis. Conceivably, then, myocardial function, particularly with stress intervention, improves in the convalescent phase after infarction because of improved perfusion.

There are certain limitations in our study. All patients had myocardial infarction in Killip class I and II and were therefore highly selected. The improved perfusion we noted after infarction does not therefore necessarily apply to other subgroups. In addition, our study was designed to be noninvasive and therefore we do not have angiographic correlates.

In conclusion, our results indicate that thallium scintigraphy may be used serially after infarction to detect improvement in perfusion which occurs in some patients after uncomplicated myocardial infarction. This improved perfusion produces resolution of residual ischemic myocardium and may thus have a protective effect. Moreover, this increased perfusion may be an important factor accounting for improvement in ventricular function in some patients in the first year after infarction. Thus, the effect of exercise programs and of drug and surgical interventions on myocardial perfusion must be interpreted cautiously within the first 12 weeks after myocardial infarction.

Assessment of the Use of the Age- and Sex-Specific United States Population as a Control Group for Analysis of Survival in Coronary Artery Disease

ROBERT M. CALIFF, MD, KERRY L. LEE, PhD, FRANK E. HARRELL, Jr, PhD, SUE Y. S. KIMM, MD, SEYMOUR GRUFFERMAN, MD, and ROBERT A. ROSATI, MD

The use of the age- and sex-specific U.S. population as a control group for analysis of survival in coronary artery disease was assessed. Population-based survival rates were calculated for nonsurgically treated patients evaluated for coronary artery disease at Duke University Medical Center. Survival of the overall group of medically treated patients with significant coronary artery disease was lower than the corresponding age- and sex-specific U.S. population rates. However, survival of patients with significant disease who had normal left ventricular contraction and stable chest pain was similar to the age- and sex-specific population survival rates. Both the observed survival and the population-based survival estimates for patients with normal left ventricular contraction and stable pain were lower than the survival of patients with normal coronary arteriograms. Even after deaths from ischemic heart disease are eliminated from the population rates, survival of patients with normal coronary arteries exceeded the age- and sex-specific population survival. Because of biases inherent in the selection of patients for cardiac catheterization and the presence of other serious diseases in persons in the general population, the age- and sex-specific U.S. population is not an adequate control group for rigorous analysis of the effect of therapy in coronary artery disease.

With the widespread use of new therapies in coronary artery disease, intense interest in the effects of these therapies on longevity has developed. Randomized and observational studies have clarified the role of specific treatments in particular subgroups of patients. For example, coronary artery bypass surgery prolongs survival in patients with left main coronary disease,[1] and beta-adrenergic blocking drugs prolong survival in some groups of patients after myocardial infarction.[2,3] These studies used concurrent patients for comparison who either were not treated or were given a specified alternative therapy. However, many large series of patients receiving a particular therapy, such as coronary artery bypass grafting, were studied in the absence of a comparable concurrent group of patients who did not receive the therapy.[4,5] In an effort to obtain a group for comparison, expected survival based on the age- and sex-specific U.S. population has been used in some instances.[6,7] The purpose of this study was to examine the use of the age- and sex-specific U.S. population mortality data as a standard against which to compare outcomes in patients with coronary artery disease.

Methods

Information system and patient population: Since 1969 at Duke University Medical Center, a comprehensive set of data has been collected on every patient undergoing cardiac catheterization.[8] Descriptors of the history, risk factors,

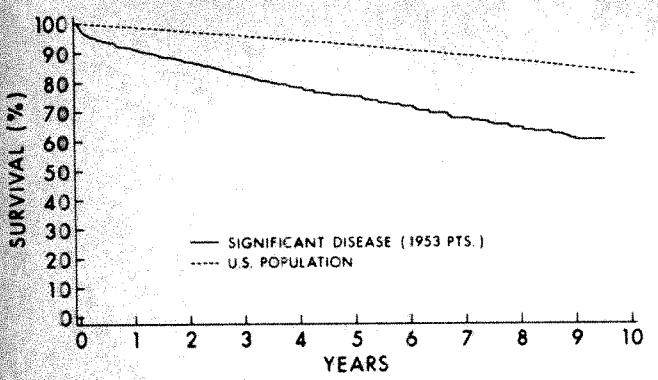

FIGURE 1. Survival in patients with significant coronary artery disease treated nonsurgically and the expected survival for these patients based on the age- and sex-specific U.S. population.

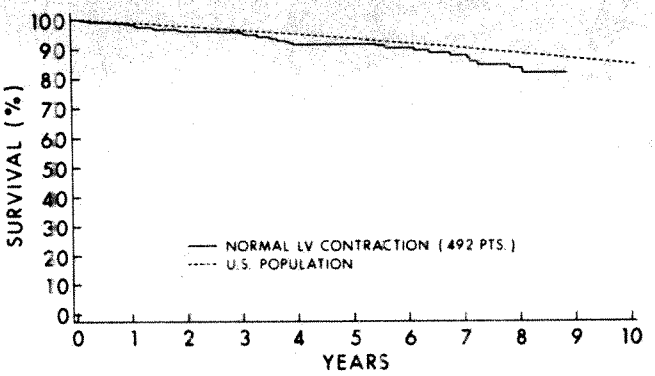

FIGURE 2. Survival in patients with significant coronary artery disease, stable chest pain, and normal left ventricular (LV) contraction and their expected survival based on the age- and sex-specific U.S. population.

physical examination, chest X-ray, electrocardiogram, and cardiac catheterization were recorded prospectively. In patients who underwent exercise testing, ambulatory monitoring, or cardiac imaging, the pertinent data were also collected. Follow-up information on survival status, occurrence of myocardial infarction, hospitalization, and chest pain was obtained at 6 months and 1 year after catheterization and at yearly intervals thereafter. Overall, follow-up study was 99% complete. To date, this information has been collected on 5,700 patients.

In this study, patients with congenital or valvular heart disease other than mitral valve prolapse or mitral regurgitation secondary to ischemic heart disease were excluded. Significant coronary artery disease was defined as ≥75% stenosis of a major coronary vessel (main left, left anterior descending or large diagonal branch, left circumflex or large marginal branch, or right coronary artery). Stable angina was defined as angina that had not been increasing in duration, severity, or frequency in the 6 weeks before cardiac catheterization. Normal left ventricular contraction was defined as the absence of contraction abnormality on the left ventriculogram at cardiac catheterization in the subjective opinion of 3 experienced angiographers.

U.S. population data: In each patient group for which an age- and sex-specific U.S. life table survival curve was calculated, the following procedure was used. For each individual patient, the age- and sex-specific probability of survival at yearly intervals through 10 years from the time of cardiac catheterization was calculated. These individual probabilities were then averaged for all patients in the group to produce population-based life table survival estimates for that particular group. Survival probabilities were calculated for all causes of death and for death from causes other than ischemic heart disease. U.S. age- and sex-specific life table mortality data published in 1975 by the National Center for Health Statistics formed the basis for these calculations.[9,10] These published mortality figures were derived from data of the 1970 population census and actual deaths that occurred in the U.S. from 1969 through 1971. The actual observed mortality experience of the patients was summarized using Kaplan-Meier life table survival estimates.[11]

Results

Figure 1 depicts the overall survival of 1,953 nonsurgically treated patients with significant coronary artery disease compared with the estimated survival based on U.S. population data. All causes of death are included. Overall, patients with significant coronary disease are at increased risk of death compared with the general population. At 1 year after catheterization, survival of patients with coronary artery disease was 91% compared with an estimated 99% 1-year survival based on the age- and sex-specific U.S. population. The 5-year survival of patients with coronary artery disease was 75%, whereas the expected survival based on U.S. population data was 92%.

Survival in 492 patients with normal left ventricular contraction, stable angina, and significant coronary disease treated nonsurgically compared with their expected survival based on age- and sex-specific population data is shown in Figure 2. The survival curves are almost identical. At 1 year the observed survival is 98% and at 5 years the survival is 92%. This figure demonstrates that in patients with significant coronary artery disease treated nonsurgically, the survival of particular subgroups can be similar to the expected survival based on population data.

Figure 3 shows the same curves as Figure 2 along with the survival of the 1,281 patients at our institution with normal coronary arteries and no other significant heart disease at cardiac catheterization. Survival in patients catheterized for chest pain and found to have normal coronary arteries is superior to both the observed survival and to the age- and sex-specific population survival in patients with significant coronary artery disease, normal left ventricular contraction, and stable angina. Thus, although survival in this subgroup of patients compares favorably with population data, we cannot conclude that therapy has eliminated the risk from ischemic heart disease in these patients.

One factor contributing to greater survival in patients with normal coronary arteries when compared with the age- and sex-specific U.S. population is the selection of patients for cardiac catheterization based on the absence of other serious illnesses. To demonstrate this point, survival in patients with normal coronary arteries at catheterization is compared in Figure 4 with their

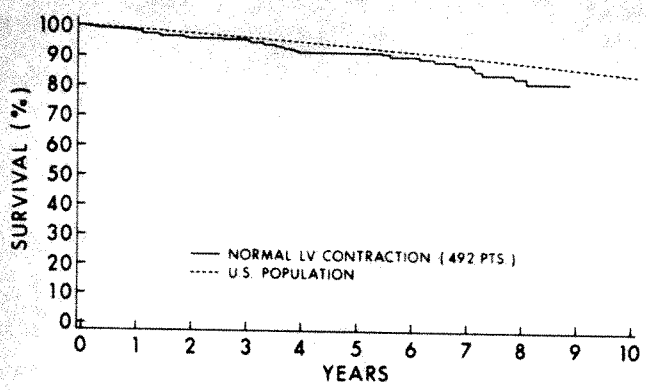

FIGURE 3. Survival in patients with significant coronary artery disease, stable chest pain, and normal left ventricular contraction, their expected survival based on the age- and sex-specific U.S. population, and survival in patients with normal coronary arteries and no other significant heart disease.

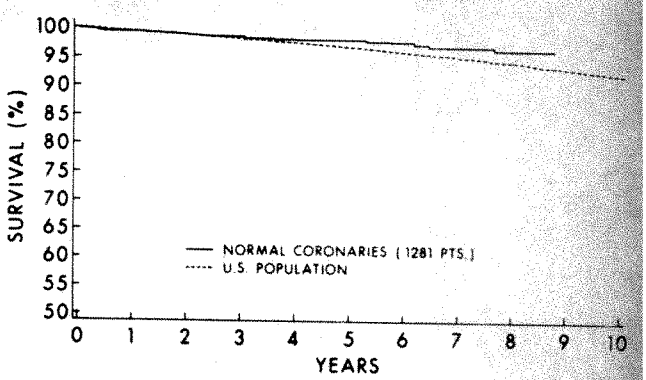

FIGURE 4. Survival in patients with normal coronary arteries and their expected survival based on general population data after excluding deaths from ischemic heart disease.

expected survival based on population data, excluding deaths from ischemic heart disease. Although the difference in survival is small, patients with normal coronary arteries at catheterization have a lower mortality from other causes of death. In our entire population of over 5,700 patients undergoing cardiac catheterization, only 79 deaths were from causes other than ischemic heart disease.

Discussion

Patients with coronary artery disease are at increased risk of death compared with the expected survival of the general U.S. population matched for age and sex (Fig. 1). The patients in this figure represent a wide spectrum of clinical conditions. Of these patients 60% had at least 1 area of abnormal left ventricular contraction and 44% had 3-vessel coronary disease. The manner in which these patients were treated also was not uniform. Most were referred for evaluation to our institution from a broad regional area and returned to the care of their local physician after cardiac catheterization. These patients received a variety of pharmacologic agents and other therapies such as exercise training. Instead of medical therapy, the term nonsurgical therapy provides a better description of the treatment these patients received, because their common feature was their nonsurgical treatment.

Despite decreased survival in the overall group of nonsurgically treated patients, patients selected with particular functional characteristics have a survival comparable to that expected from age- and sex-specific population data (Fig. 2). The particular group of patients with normal left ventricular function and stable angina was chosen only for the purpose of demonstration. Similar results can be demonstrated in patient subgroups defined by other factors such as the number of diseased vessels, history of previous infarction, and exercise test results. The implication of this finding is that clinical, anatomic, and ventricular function status at cardiac catheterization can cause survival to vary widely. Thus, a group of patients with coronary artery disease may have survival similar to the expected survival based on age- and sex-specific U.S. population data even without a particular therapy such as bypass surgery. In institutions in which patients undergo cardiac catheterization early in the course of their disease, a large percentage of patients may have good ventricular function, stable symptoms, and involvement of only 1 or 2 coronary arteries. These patients would be expected to have excellent survival whether treated surgically or nonsurgically.

Figure 3 demonstrates that although a subgroup of patients may have survival equal to the expected survival based on population data, the risk of death from ischemic heart disease has not been eliminated by medical therapy. If the risk of death from ischemic heart disease were eliminated, survival of patients with coronary artery disease should equal that of patients who underwent catheterization and were found to have no coronary artery disease.

The difference in survival between patients with normal coronary arteries and the U.S. population curve can be explained by 2 factors. First, deaths from ischemic heart disease account for a large proportion of deaths in the general population. Obviously, almost no cardiac deaths occurred in our patients with normal coronary arteries. Second, patients undergoing cardiac catheterization are a selected group not only because of chest pain, but also because of the relative absence of other life-threatening illnesses such as cancer and end-stage lung disease.

Figure 4 demonstrates that patients undergoing cardiac catheterization are at lower risk of competing causes of death compared with people in the general population matched for age and sex. Although the observed difference in survival is small after excluding deaths from ischemic heart disease from the population data, it underscores the fact that patients with coronary disease are not strictly comparable to the general population. The selection of patients for catheterization is

based on multiple factors. The absence of other significant life-threatening illnesses may be an important selection bias.

One purpose of comparing the survival of different populations is to gain a general understanding of the outcome of a particular disease. The clinician may approach the patient with coronary disease somewhat differently with the understanding that the survival of selected groups of patients after cardiac catheterization is similar to that of the age- and sex-specific U.S. population. In particular, in the present study, we demonstrated that medically treated patients with good ventricular function and stable chest pain have survival similar to that of the age- and sex-specific population. Therefore, every patient with coronary disease need not feel that death is imminent, and the physician need not always feel that urgent action is needed.

Finally, population mortality data should not be used to determine the efficacy of therapy. Depending on the referral patterns of an institution and the selection process by which patients are given specific therapy, characteristics of the patient series studied may vary widely. We have demonstrated that these characteristics, such as baseline ventricular function and stability of angina, have a profound effect on the relative survival of patients managed medically compared with that of the age- and sex-specific U.S. population. Whether the therapy being investigated is pharmacologic or coronary artery bypass grafting, we cannot assume that if patients who receive the therapy have longevity comparable with age- and sex-specific population data, patients who do not receive the therapy would have a survival less than that of the U.S. population. Therefore, only patient populations in which prognostic characteristics have been carefully documented and adjusted for to insure comparability can be used for comparison to determine therapeutic efficacy. Furthermore, patients having cardiac catheterization are a selected group and are not comparable to the general population with regard to other causes of death.

BIOTRONIK

Pacers in a class of their own™

Kalos

a multi-programmable pacer with unique clinical features

- The thinnest pacer you can implant (only 8.8. mm) with an optimized geometrical shape* for more patient comfort
- Multi-programmable in all important parameters, V00/VVI, M
- Programmable high output
- Long service life
- The high reliability you have experienced with all BIOTRONIK pacers and products
- Available for unipolar and bipolar stimulation

BIOTRONIK pacers combined with the various BIOTRONIK active and passive fixation leads provide integrated pacing systems with the assurance of maximum reliability since all parts match one another and allow you to decide which system best suits the needs of each individual patient

*Also available with the same thin, optimized geometrical shape, the standard VVI pacers **LEUKOS** and **LEIOS.**

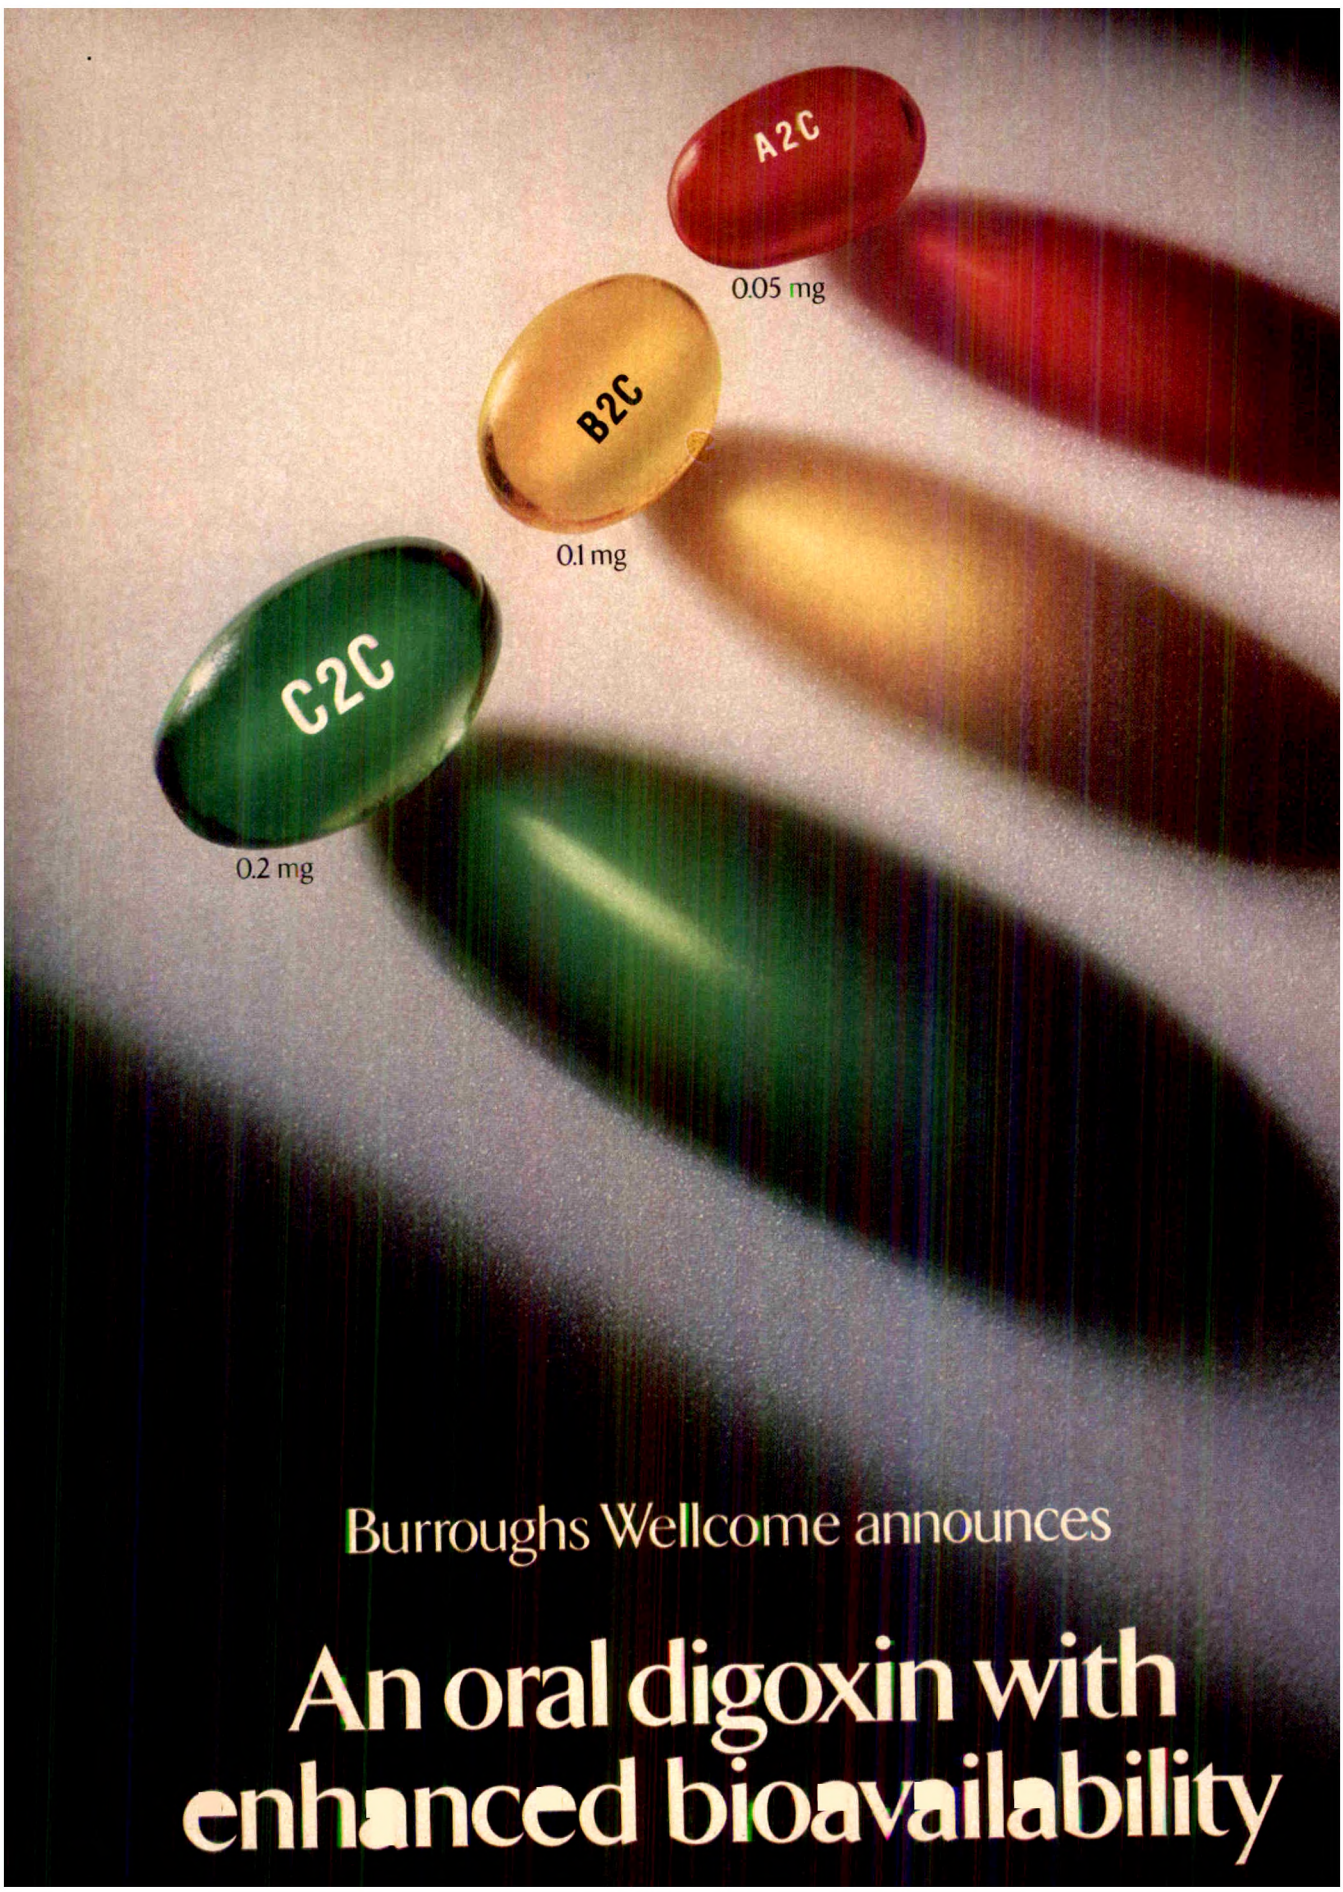
Kalos



Burroughs Wellcome announces

An oral digoxin with enhanced bioavailability

Absorption of digoxin from LANOXICAPS® is 90-100% complete!

The enhanced digoxin absorption from LANOXICAPS® compared to tablets and elixir is associated with reduced between-patient and within-patient variability in steady-state serum concentrations.

Comparison of bioavailability and equivalent doses				
Product	Bioavailability	Equivalent Doses (in MG)*		
Lanoxin® Tablet	60-80%	0.125	0.25	0.5
Lanoxin® Elixir	70-85%	0.125	0.25	0.5
Lanoxin® Injection/IM	70-85%	0.125	0.25	0.5
Lanoxin® Injection/IV	100%	0.1	0.2	0.4
LANOXICAPS® Capsules	90-100%	0.1	0.2	0.4

*1 mg = 1,000 μg

Due to the more complete absorption of digoxin from Lanoxicaps, recommended oral doses are 80% of those for tablets, elixir, and IM injection.

Lanoxicaps may help make a smoother transition for patients who are being switched from intravenous to oral therapy. Also, consider Lanoxicaps for all your newly diagnosed patients.

Colors of Lanoxicaps are distinctive, for less confusion or misidentification by patients. Please see next page for brief summary of prescribing information.

Brief Summary of Prescribing Information

INDICATIONS AND USAGE
Heart Failure: The increased cardiac output resulting from the inotropic action of digoxin ameliorates the disturbances characteristic of heart failure (venous congestion, edema, dyspnea, orthopnea and cardiac asthma).

Digoxin is more effective in "low output" (pump) failure than in "high output" heart failure secondary to arteriovenous fistula, anemia, infection or hyperthyroidism.

Digoxin is usually continued after failure is controlled, unless some known precipitating factor is corrected. Studies have shown, however, that even though hemodynamic effects can be demonstrated in almost all patients, corresponding improvement in the signs and symptoms of heart failure is not necessarily apparent. Therefore, in patients in whom digoxin may be difficult to regulate, or in whom the risk of toxicity may be great (e.g., patients with unstable renal function or whose potassium levels tend to fluctuate) a cautious withdrawal of digoxin may be considered. If digoxin is discontinued, the patient should be regularly monitored for clinical evidence of recurrent heart failure.

CONTRAINDICATIONS
Digitalis glycosides are contraindicated in ventricular fibrillation.

Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin, as is hypersensitivity to digoxin itself. Allergy to digoxin, though rare, does occur. It may not extend to all preparations, and another digitalis glycoside may be tried with caution.

WARNINGS
The use of digoxin or other digitalis glycosides is unwarranted in the treatment of obesity.

Digoxin in soft capsules should be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate.

Anorexia, nausea, vomiting, and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity. Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS
General: Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range," because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B, or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see *Treatment of arrhythmias produced by overdosage*, in OVERDOSAGE section).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the quinidine dose. Because of the considerable variability of this interaction, digoxin dosage should be carefully individualized.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (eg, hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e., sick sinus syndrome), digoxin may worsen sinus bradycardia or sinoatrial block.

In patients with Wolff-Parkinson-White syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

Drug Interactions: Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. *Antacids, kaolin-pectin, sulfasalazine, neomycin,* and *cholestyramine* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although *propranolol* and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

ADVERSE REACTIONS
The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5% to 20%, with 15% to 20% being considered serious (1% to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

Adults:
Cardiac—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm, and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage.

Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

Gastrointestinal—Anorexia, nausea, vomiting, and, less commonly, diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

CNS—Visual disturbances (blurred or yellow vision), headache, weakness, apathy, and psychosis can occur.

Other—Gynecomastia is occasionally observed.

Infants and Children:
Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea, and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular

arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first-degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

OVERDOSAGE Treatment of arrhythmias produced by overdosage

Adults:

Digoxin should be discontinued until all signs of toxicity are gone. Discontinuation may be all that is necessary if toxic manifestations are not severe.

Potassium salts are commonly used, particularly if hypokalemia is present. Potassium chloride in divided oral doses totaling 3 to 6 grams of the salt (40 to 80 mEq K+) for adults may be given provided renal function is adequate (see below for potassium recommendations in infants and children).

When correction of the arrhythmia is urgent and the serum potassium concentration is low or normal, potassium should be administered intravenously in 5% dextrose injection. For adults, a total of 40 to 80 mEq (diluted to a concentration of 40 mEq per 500 ml) may be given at a rate not exceeding 20 mEq per hour, or slower if limited by pain due to local irritation. Additional amounts may be given if the arrhythmia is uncontrolled and potassium well tolerated. ECG monitoring should be performed to watch for any evidence of potassium toxicity (e.g., peaking of T waves) and to observe the effect on the arrhythmia. The infusion may be stopped when the desired effect is achieved.

Note: Potassium should not be used and may be dangerous in heart block due to digoxin unless primarily related to supraventricular tachycardia.

Other agents that have been used for the treatment of digoxin intoxication include lidocaine, procainamide, propranolol, and phenytoin, although use of the latter must be considered experimental. In advanced heart block, temporary ventricular pacing may be beneficial.

Infants and Children:

See Adults section (immediately above) for general recommendations for the treatment of arrhythmias produced by overdosage and for cautions regarding the use of potassium.

If a potassium preparation is used to treat toxicity, it may be given orally in divided doses totaling 1 to 1.5 mEq K+ per kilogram (kg) body weight (1 gram of potassium chloride contains 13.4 mEq K+).

When correction of the arrhythmia with potassium is urgent, approximately 0.5 mEq/kg of potassium per hour may be given intravenously, with careful ECG monitoring. The intravenous solution of potassium should be dilute enough to avoid local irritation; however, especially in infants, care must be taken to avoid intravenous fluid overload.

DOSAGE AND ADMINISTRATION

Recommended dosages are average values that may require considerable modification because of individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended doses.

Due to the more complete absorption of digoxin from soft capsules, recommended oral doses are only 80% of those for tablets, elixir, and IM injection.

Because the significance of the higher peak serum concentrations associated with once-daily capsules is not established, divided daily dosing is presently recommended for:

1. infants and children under 10 years of age;
2. patients requiring a daily dose of 300 μg (0.3 mg) or greater;
3. patients with a previous history of digitalis toxicity;
4. patients considered likely to become toxic;
5. patients in whom compliance is not a problem.

Where compliance is considered a problem, once-daily dosing may be appropriate.

Adults:

Adults: rapid digitalization with a loading dose—Peak body digoxin stores of 8 to 12 μg/kg should provide therapeutic effect with minimum risk of toxicity in most patients with heart failure and normal sinus rhythm. Larger stores (10 to 15 μg/kg) are often required for adequate control of ventricular rate in patients with atrial flutter or fibrillation. Because of altered digoxin distribution and elimination, projected peak body stores for patients with renal insufficiency should be conservative (i.e., 6 to 10 μg/kg [see PRECAUTIONS section]).

The loading dose should be based on the projected peak body stores and administered in several portions, with roughly half the total given as the first dose. Additional fractions of this planned total dose may be given at 6- to 8-hour intervals, *with careful assessment of clinical response before each additional dose.*

If the patient's clinical response necessitates a change from the calculated dose of digoxin, then calculation of the maintenance dose should be based upon the amount actually given.

Dosage for Previously Undigitalized Patients:

In previously undigitalized patients, a single initial Lanoxicaps dose of 400 to 600 μg (0.4 to 0.6 mg) usually produces a detectable effect in 0.5 to 2 hours that becomes maximal in 2 to 6 hours. Additional doses of 100 to 300 μg (0.1 to 0.3 mg) may be given cautiously at 6- to 8-hour intervals until clinical evidence of an adequate effect is noted. The usual amount of Lanoxicaps that a 70-kg patient requires to achieve 8 to 15 μg/kg peak body stores is 600 to 1000 μg (0.6 to 1.0 mg).

Adults: gradual digitalization with a maintenance dose—The following table provides average Lanoxicaps daily maintenance dose requirements for patients with heart failure based upon lean body weight and renal function:

Usual Lanoxicaps Daily Maintenance Dose Requirements (μg) for Estimated Peak Body Stores of 10 μg/kg

Corrected Ccr (ml/min per 70 kg)	Lean body weight (kg/lbs) 50/110	60/132	70/154	80/176	90/198	100/220	Number of days before steady-state achieved
0	50	100	100	100	150	150	22
10	100	100	100	150	150	150	19
20	100	100	150	150	150	200	16
30	100	150	150	150	200	200	14
40	100	150	150	200	200	250	13
50	150	150	200	200	250	250	12
60	150	150	200	200	250	300	11
70	150	200	200	250	250	300	10
80	150	200	200	250	300	300	9
90	150	200	250	250	300	350	8
100	200	200	250	300	300	350	7

Example—Based on the above table, a patient in heart failure with an estimated lean body weight of 70 kg and a Ccr of 60 ml/min should be given 200 μg (0.2 mg) of Lanoxicaps per day, usually taken as a 100 μg (0.1 mg) capsule after the morning and evening meals. Steady-state serum concentrations should not be anticipated before 11 days.

Digitalizing Dose for Children:

Usual Digitalizing and Maintenance Dosages for Lanoxicaps in Children With Normal *Renal Function Based on Lean Body Weight*

Age	Digitalizing* Dose (μg/kg)	*Daily*† Maintenance Dose (μg/kg)
2-5 Years	25-35	25%-35% of the oral or IV loading dose‡
5-10 Years	15-30	
Over 10 Years		

*IV digitalizing doses are the same as Lanoxicaps digitalizing doses.

†Divided daily dosing is recommended for children under 10 years of age.

‡Projected or actual digitalizing dose providing desired clinical response.

More gradual digitalization can also be accomplished by beginning an appropriate maintenance dose. The range of percentages provided above can be used in calculating this dose for patients with normal renal function. In children with renal disease, digoxin dosing must be carefully titrated based upon desired clinical response.

Long-term use of digoxin is indicated in many children who have been digitalized for acute heart failure, unless the cause is transient. Children with severe congenital heart disease, even after surgery, may require digoxin for prolonged periods.

It cannot be overemphasized that both the adult and pediatric dosage guidelines provided are based upon average patient response and substantial individual variation can be expected. Accordingly, ultimate dosage selection must be based upon clinical assessment of the patient.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

Norpace (disopyramide phosphate) 100-mg and 150-mg capsules

Norpace CR controlled release (disopyramide phosphate) 100-mg and 150-mg capsules

for the long term

Before prescribing, please consult current complete prescribing information, a summary of wh follows: **Indications:** For suppression and prevention of recurrence of the following cardiac ar rhythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. I is also equally effective in treating primary cardiac arrhythmias and those which occur in asso ation with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patient with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogen shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negativ inotropic properties. Hypotension has been observed primarily with primary cardiomyopath or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Pro longation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may b at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues the patients should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of drug unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace or Norpace CR therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Therefore, a loading dose of Norpace should not be given to such patients, and initial dosage and subsequent dosage adjustments should be made under close supervision. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs for overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin or other hepatic enzyme inducers may cause lower disopyramide plasma levels; whereas with quinidine, disopyramide levels may increase and quinidine levels may decrease. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day given in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete prescribing information for dosage recommendations.**

New Norpace® CR controlled release

(disopyramide phosphate)

100-mg and 150-mg capsules

Simple dosage schedule *Just two capsules b.i.d. reduce the potential for skipped doses*

Enhanced compliance *Norpace CR helps to establish continuous effective dysrhythmia therapy... especially well suited to long-term use.*

Effective dysrhythmia therapy *Bioavailability studies demonstrate that Norpace CR q12h provides therapeutic blood levels equivalent to immediate-release Norpace (disopyramide phosphate) q6h, with less variability.*

The most commonly seen side effects from disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties. Please see the brief summary of prescribing information on the preceding page.

Improved Radiation Protection for Physicians Performing Cardiac Catheterization

EDWARD W. GERTZ, MD, JUDITH A. WISNESKI, MD, ROBERT G. GOULD, ScD, and JOHN R. AKIN, MD

Physicians and their assistants performing diagnostic angiography must be concerned with the radiation exposure they receive. The introduction of hemiaxial projections for imaging has increased diagnostic accuracy but has also greatly increased the physicians' exposure to scattered radiation. This increase is especially critical for the eyes and thyroid of the physician who routinely performs these procedures. To reduce such exposure a ceiling-suspended shield (60 × 45 cm), made of 6.4 mm glass with a 19.5 kg/m^2 (4 lb/ft^2) lead equivalency, was developed. During procedures the shield is interposed between the physician and the region of the patient acting as the source of scattered radiation. The degree of radiation protection to the operator was assessed by measuring the distribution of scattered radiation in the vicinity of the operator with and without the shield. The effectiveness of the shield was determined in the 30° right anterior oblique (RAO), 5° left anterior oblique (LAO), 35° LAO, and 50° LAO-15° cranial angulations. At critical heights such as the level of the eyes and thyroid, scattered radiation levels were reduced by 85% or greater in all angulations. Without interfering with the physician's ability to observe the patient or manipulate the catheter, this shield can significantly reduce the physician's exposure to radiation.

Several investigations have measured radiation exposure to the physician during cardiac catheterization and coronary angiography.[1-7] Most of these investigations were performed using a fixed undertable x-ray tube or a U-arm system. The exposure levels reported in these studies are excessive for physicians who perform angiography routinely. Guidelines have been established for occupational radiation exposure.[8] Because of exposure to critical organs such as the eyes and thyroid, compliance with these guidelines may require that the physician perform only several procedures a week.[1,2]

Radiographic systems with high output capacity generators and x-ray tubes have recently been introduced, thus providing the potential for better definition of vessels and lesions on cineangiography. In addition, C-arm and parallelogram support structures are being used which allow the physician to easily obtain hemiaxial views. These developments enhance the diagnostic accuracy of coronary angiography[9-11]; however, the radiation exposure to the operator is potentially greater with these systems than with older undertable-mounted x-ray tube systems.

To reduce the physician's radiation exposure, a protective shield was developed in the cardiac catheterization laboratory at the San Francisco Veterans Administration Medical Center. The purpose of this study was to assess the effectiveness of this shield in reducing the radiation exposure to the physician performing cardiac catheterization with a poly C-arm system.

Methods

The radiographic equipment consists of a Poly Diagnost C System and a Maximus M-100 Generator (Philips Medical Systems). The Poly Diagnost C has a U-arm type imaging system with a parallelogram support. In addition to the left-right rotation of the x-ray tube and intensifier, the parallelogram support allows isocentric cranial and caudal angulation.

The radiation protection shield (Fig. 1) is made of transparent 6.4 mm glass (60 × 45 cm) with a 19.5 kg/m^2 (4 lb/ft^2) lead equivalency. Attached to the bottom of the glass is a piece of flexible leaded rubber 22 cm long with 19.5 kg/m^2 lead equivalency.

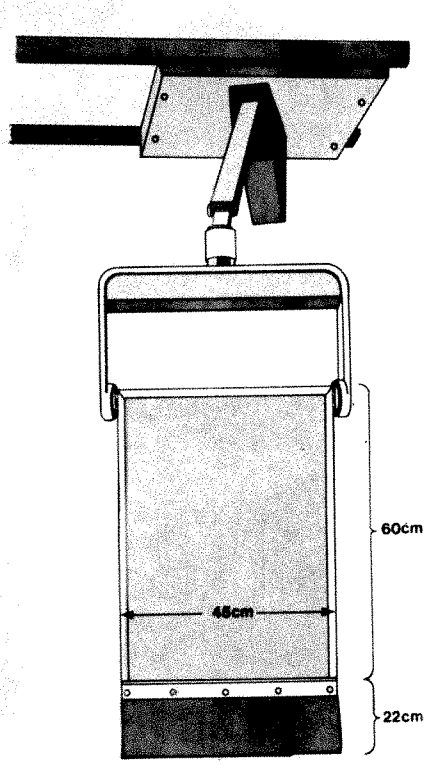

FIGURE 1. Diagram of the radiation protection shield with ceiling mount.

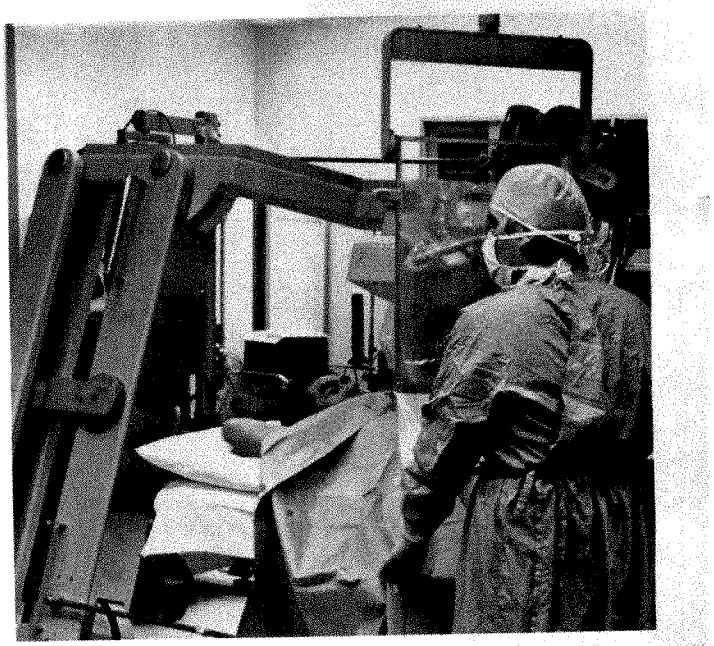

FIGURE 2. Photograph illustrating the use of the shield during cardiac catheterizations performed through the femoral approach.

The shield is mounted on ceiling rails with a swivel arm allowing for easy mobility in the longitudinal and vertical planes. In addition, it is counterbalanced to allow for easy vertical movement. During procedures the shield is draped with a sterile, transparent cover. Therefore, the physician performing the procedure can position the shield between himself and the x-ray scattering source (patient and x-ray tube) (Fig. 2). The flexible leaded rubber attached to the bottom of the glass is designed to lie on the patient, thus providing additional protection by eliminating the scattered radiation which would reach the operator beneath the leaded glass.

The radiation protection afforded by the shield was determined by measurements of radiation levels in the vicinity of the operator with and without the shield in place. A Rando anthropomorphic phantom was used in this study. This whole body phantom contains human bones and is comprised of materials which simulate human soft tissue. Its shape is that of an adult male weighing 70 kg with a 22 cm chest diameter. The radiation levels were measured with a Victoreen Panoramic survey meter during fluoroscopy at 95 kVp and 1 mA. The effectiveness of the shield was determined with the x-ray tube aligned in the following projections: 30° RAO, 5° LAO, 35° LAO, and 50° LAO-15° cranial angulation.

Results

Table I gives a comparison of radiation exposure levels for the various anatomic locations of the operator without and with the shield. The values listed are for an operator who is 5 feet, 10 inches tall and standing in the position shown in Figure 2 with the height of the catheterization table at 90 cm. These radiation levels were obtained with the phantom simulating the patient. As shown in Table I, there is a significant reduction in radiation exposure afforded by the shield to all anatomic areas above and including the pelvis. For the eyes and thyroid, which are of critical concern, there was an 85% or greater reduction in exposure levels for all angulations.

To further illustrate the effectiveness of this shield, the isoexposure curves for the 50° LAO-15° cranial angulation are shown in Figure 3. This angulation is commonly used during cardiac cineangiography to better visualize the left main coronary artery, the proximal left anterior descending artery, and the distal right coronary artery. Using this cranial angulation, the eyes and thyroid of the operator are exposed to 41 mR/h during fluoroscopy at 95 kVp and 1 mA. For a 10 second cineangiogram at 30 frames/s and 2.8 mAs/frame, the exposure to the eyes and thyroid of the operator would be 9.6 mR. For an identical angiogram with the x-ray tube in the same projection, use of the protective shield would reduce the exposure to these organs to 0.2 mR.

It should be noted that the effectiveness of the shield does not significantly depend on the x-ray tube potential. The equivalent lead thickness of this shield is 1.58 mm. Thus, even for x-rays of 150 kV, less than 3% will penetrate the glass.

Discussion

Concern has been expressed over the radiation exposure to physicians performing cardiac catheterizations. Previous studies have documented that the physician performing catheterization and his assistant can receive significant radiation exposure.[1–7] The irradiation of the physician primarily results from scattered radiation arising within the patient from the tissues penetrated by the primary beam. The exposure received during 1 second of fluoroscopy is approximately equal to that received during 1 cineangiographic frame. Thus,

TABLE I Radiation Exposure Levels (milliroentgen/hour)

Anatomic Location	X-Ray Tube Angulation			
	30° RAO: Without/With Shield	5° LAO: Without/With Shield	35° LAO: Without/With Shield	50° LAO-15° Cranial: Without/With Shield
Eyes, thyroid	3.8/0.5	12/0.6	25.5/0.5	41/0.7
Chest	6.5/0.7	18.5/0.8	33/0.7	58/0.7
Pelvis	10/1.4	18.5/5.9	27/5.7	57/3.2
Lower legs	38/36	31/31	45/45	2.5/1.8

during a cardiac catheterization, 50 to 80% of the physician's exposure occurs during cineangiography.[1,2] The actual exposure level will vary depending on the radiographic equipment and the type of procedure involved. With the advent of C-arm and parallelogram-supported imaging systems to obtain the hemiaxial views, exposure levels to the physician can be increased; greater emphasis should be placed on the radiation protection of physicians routinely performing cardiac catheterizations.

This study measured the radiation exposure levels for physicians using a Philips Poly Diagnost C System in 4 different angulations. As shown in Table I, the LAO-cranial angulation has the greatest potential for exposure to the physician's chest, eyes, and thyroid. The thyroid and the lens of the eye, which are not shielded by the routine lead apron, remain the most critical organs for radiation exposure for individuals routinely performing catheterization. Radiation-induced cataracts are well described in animals and humans who are chronically exposed to ionizing radiation; the dose-response curve appears to have a threshold.[12] There is a higher incidence of thyroid carcinoma in persons exposed to both therapeutic and occupational radiation; this probably follows a linear dose-response curve.[12] The maximal exposure recommended is 5 R/year (100 mR/wk) for the lens of the eye and 15 R/year (300 mR/week) for the thyroid.[8]

Protection devices are available for individual organs: thyroid shields and leaded eyeglasses. However, eyeglasses are only effective in protecting the lens of the eye from scattered radiation when the operator is looking in the direction of the source of radiation, that is, looking directly at the part of the patient that is being irradiated. Generally the physician is watching the television monitor during fluoroscopy or cineangiography. Thus, the eyeglasses may not be effective in reducing exposure to this organ. The shield described in this report protects these individual organs while decreasing the general exposure to the pelvis, chest, and face.

In addition to the protective devices for the individual organs, other shields or screens have been designed to decrease the operator's exposure.[2,3,13] In order to be of value, the device or shield must exhibit the following features: (1) it must be effective in reducing the scattered radiation to the operator in the various projections; (2) it must not interfere with patient care and catheter manipulation; and (3) it must be easy and comfortable for the operator to use. The protective

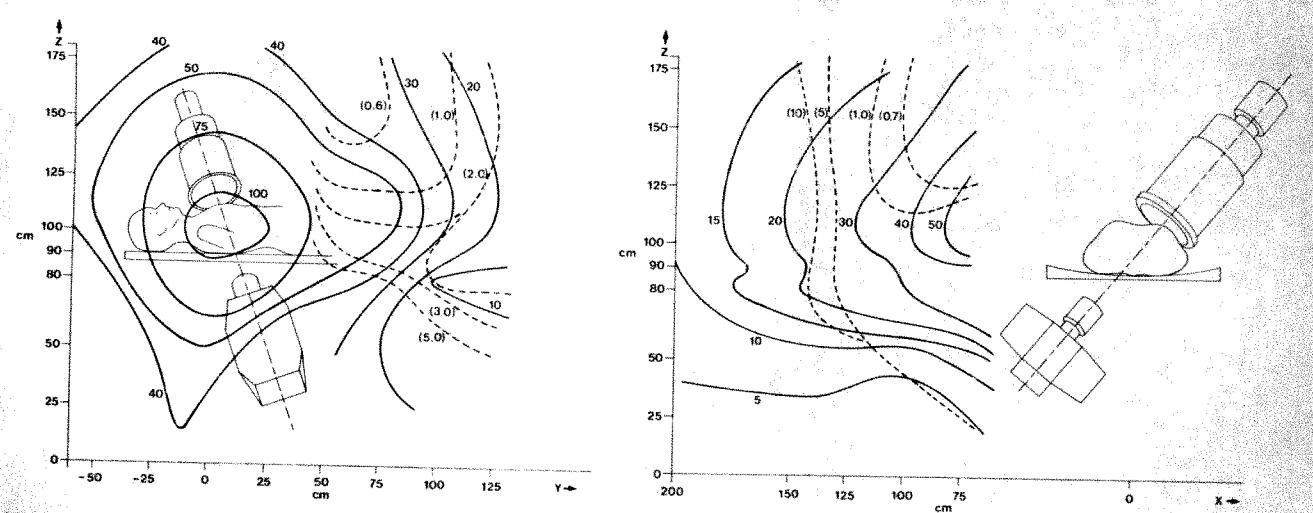

FIGURE 3. Isoexposure curves expressed in milliroentgen/hour for the 50° LAO-15° cranial angulation in (**left**) the longitudinal plane with the operator at 75 cm on the Y axis, and (**right**) the horizontal plane with the operator at 75 cm on the X axis. The **solid lines** give the radiation exposure levels *without* the protection of the shield; the **dashed lines** show the values *with* the shield. The vertical center of shield is at 75 cm in both the X and Y planes with the operator behind the shield as shown in Figure 2. Z represents the vertical plane, Y the longitudinal plane, and X the horizontal plane.

shield described in this report meets these criteria. This shield reduces the physician's exposure to the eyes and thyroid by at least 85% in all views (Table I). For example, during fluoroscopy at 95 kVp and 1 mA in the LAO-cranial angulation, it reduces the exposure level from 41 to 0.7 mR/hour. This shield is thus effective in reducing the scattered radiation to the thyroid and the eyes of physicians performing cardiac catheterization.

Our shield also has the second and third features described above. It is made of transparent glass and covered with a transparent, sterile cover during the procedure; thus, the physician is able to observe the patient. With the mobility afforded by the ceiling rails, swivel arm, and counterbalance, the physician can easily position the shield before fluoroscopy and cineangiography. The shield is positioned with the flexible leaded rubber on the patient's lower abdomen, so it does not interfere with catheter manipulation at the groin site. This shield has been in daily use for over 2.5 years in the cardiac catheterization laboratory at the San Francisco Veterans Administration Medical Center.

This study assesses the potential radiation exposure to physicians performing cardiac catheterization using a Poly C Diagnost System. The radiation exposure to the eyes and thyroid is considerably increased using the LAO-cranial view compared with the traditional RAO and LAO views. A leaded glass shield is described which was found to be effective in significantly reducing (>85%) the physician's radiation exposure in all angulations. In addition, this shield does not interfere with patient observation or catheter manipulation.

Compression of the Superior Vena Cava and Right Atrium In Cardiac Tamponade

STEPHEN W. MILLER, MD, LAURA FELDMAN, MD, IGOR PALACIOS, MD, ROBERT E. DINSMORE, MD, JOHN B. NEWELL, LINDA GILLAM, MD, and ARTHUR E. WEYMAN, MD

In an attempt to identify specific angiographic patterns which might be useful in distinguishing cardiac tamponade from constrictive pericarditis and other causes of right atrial hypertension, we studied the angiographic and hemodynamic characteristics of 10 patients with cardiac tamponade and compared these with similar characteristics in a comparable group of patients with either constrictive pericarditis, effusive-constrictive pericarditis, or pericardial effusion with left ventricular failure. Two predictive angiographic patterns of cardiac tamponade were noted: (1) a tapering or local lateral indentation of the intrapericardial portion of the superior vena cava, and (2) an exaggerated phasic variation in the diameter of the superior vena cava at its junction with the right atrium. Using the ratio of the minimum-to-maximum diameter of the intrapericardial superior vena cava (caval compression ratio), a stepwise logistic regression indicated that when this ratio was <0.62, cardiac tamponade was present with a sensitivity of 80%, a specificity of 90%, and a p value <0.001. The change in diameter of the superior vena cava between systole and diastole (phasic narrowing ratio) also was a discriminator of cardiac tamponade (p <0.04). Two-dimensional echocardiographic studies in an additional group of 10 patients with cardiac tamponade demonstrated marked concavity of the right atrial free wall, which corresponded temporally to the angiographic abnormality, but was even more marked than that noted on the cineangiograms. These results indicate that specific changes can be appreciated on superior vena cavography and can be useful in distinguishing cardiac tamponade from other pericardial or myocardial processes associated with right atrial hypertension.

Compression of the heart by fluid within the pericardium—cardiac tamponade—can produce major changes in the shape,[1-4] size,[1,5-11] and motion[1,6,10-14] of the 4 cardiac chambers and thereby significantly impair cardiac function. The severity of these alterations is influenced by the amount of fluid within the pericardium, the underlying disease process, and the location or loculation of the fluid. When tamponade is clinically suspected and a diagnosis cannot be made noninvasively, right heart catheterization is usually indicated for hemodynamic measurements. In addition, right atrial angiography may provide morphologic information to help establish the diagnosis.[15] Hemodynamically, tamponade is characterized by a decreased cardiac output, equalization of atrial mean and ventricular end diastolic pressures, and an absent *y* descent in the right atrial pressure tracing.[16-19] Right atrial angiography demonstrates an increased separation between the right atrial cavity and the lung, small cardiac chambers, prolonged circulation time through the heart, inferior vena caval reflux, and straightening of the lateral wall of the right atrium.[2-4,6] Unfortunately, none of these angiographic signs is specific for tamponade and similar findings may be present when there is constrictive pericarditis with pericardial thickening. Some of these findings may be present with restrictive cardiomyopathy.[3,20-23]

In order to determine whether other specific angiographic signs of tamponade exist, the angiograms of a series of patients with proven cardiac tamponade were compared with those of other patients with pericardial diseases but without hemodynamic evidence of tamponade.

Methods

Twenty patients who underwent cardiac catheterization and angiography for possible pericardial heart disease were classified on the basis of hemodynamic parameters into a group with cardiac tamponade (Group 1) and a control group with other pericardial diseases (Group 2). The age range and sex ratio were similar in both groups (Table I). The criteria for cardiac tamponade included (1) a diminutive or absent *y*

* All pressures in mm Hg. PA = pulmonary artery systolic and diastolic pressure; PCW = mean pulmonary capillary wedge pressure; RA = mean right atrial pressure; RV = right ventricular systolic and diastolic pressure.

descent in the right atrial pressure tracing, (2) equalization within 4 mm Hg of the mean right atrial, right ventricular end-diastolic, pulmonary arterial diastolic, and mean pulmonary capillary wedge pressures, and (3) the withdrawal of a significant amount of fluid during pericardiocentesis with clinical and hemodynamic improvement.

The control group had other types of pericardial heart disease. Seven patients had pericardial constriction with a prominent *y* descent and a "dip and plateau" configuration of the ventricular diastolic pressure tracing. Three patients had pericardial effusion without tamponade but with left ventricular failure. Mean right atrial pressure in Group 1 was 14 ± 3 mm Hg (mean ± standard deviation) and in Group 2 was 13 ± 6 mm Hg. Mean pulmonary capillary wedge pressure in Group 1 was 14 ± 4 mm Hg and in Group 2 was 16 ± 7 mm Hg. Neither mean right atrial nor pulmonary capillary wedge pressure was statistically different in Groups 1 and 2. One patient from Group 1 and 4 patients from Group 2 had had previous heart surgery.

Superior vena caval cineangiography was performed in the posteroanterior projection, with the catheter placed in the superior vena cava between the azygos vein and the right atrium. Contrast material was injected at a rate of 20 ml per second for 2 seconds. Filming included the superior vena cava between the azygos vein and the heart, the right atrial cavity and its wall so that the right lung could be seen, the proximal 1 to 3 cm of the inferior vena cava, and delayed visualization of the remainder of the heart. The angiograms were interpreted independently of the hemodynamic measurements.

The superior vena cava was analyzed as shown in Figure 1. Two kinds of measurement were made. The caval compression ratio was defined as the minimum diameter (c) of the right atrial-superior vena caval junction during the cardiac cycle divided by the maximum diameter (a) of the superior vena cava, which usually occurred just below the azygos vein. The phasic change in caval diameter (phasic narrowing ratio) was measured at the right atrial-superior vena caval junction and was the ratio of the minimum (c) to maximum (b) width during the cardiac cycle. The shape of the lateral right atrial cavity was graded as convex, straight, or concave. Reflux was said to occur into the inferior vena cava if at least 1 cm was opacified.

Statistical analysis consisted of the computation of a probability model for discriminating the tamponade group from the nontamponade group on the basis of predictor (angiographic) measurements. This was done by means of the BMDP program for stepwise logistic regression, BMDPLR.[24] Sensitivity and specificity of this resulting probability model were also estimated by the program. Comparison of mean predictors in the 2 groups was performed by Student's *t* test.

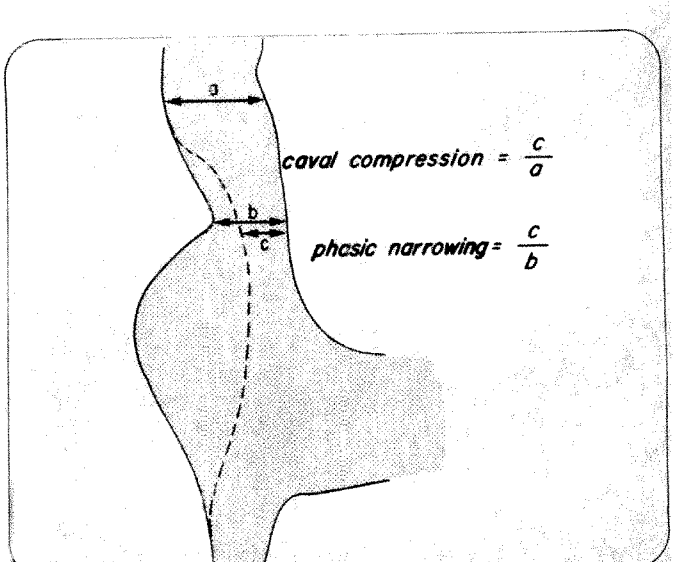

FIGURE 1. Line drawing of a superior vena caval and right atrial angiogram illustrating measurement of the caval compression and phasic narrowing ratios. The **dotted line** represents the right atrial free wall in systole.

An additional group of 10 patients with cardiac tamponade was studied by 2-dimensional echocardiography. Tamponade was defined by the same hemodynamic criteria as were used in the angiographic groups. The intrapericardial pressures were elevated, with a mean of 17 mm Hg and a range of 9 to 31 mm Hg. All patients showed hemodynamic improvement after pericardiocentesis. This group included 4 females and 6 males, with a mean age of 48 years (range 16 to 76). In each of these cases, the right atrial free wall was recorded using the conventional parasternal short-axis, apical 4 chamber, and subcostal views, and its configuration and phasic motion were examined.[25]

Results

Changes in the superior vena cava: The intrapericardial portion of the superior vena cava was distorted in all patients with cardiac tamponade. A typical superior vena caval angiogram (Fig. 2) demonstrated a long, tapered narrowing inferior to the azygos vein termination, extending inferiorly to the right atrium. The configuration of the superior vena cava varied from a symmetrical tapering to a sharply demarcated defect in its lateral wall below the right pulmonary artery (Fig. 3A) or a combination of this defect with concavity and medial displacement of the cava (Fig. 3B).

In addition to these changes in the configuration of the superior vena cava, there was an exaggerated variation in caval diameter which changed with the cardiac cycle. Cineangiograms taken during tamponade characteristically demonstrated increased narrowing of the intrapericardial superior vena cava throughout atrial systole (Fig. 4). The extent of this phasic narrowing varied; in 1 case the lumen of the cava measured 5 mm after correction for magnification. In contrast, the caval angiograms in patients with pericardial effusion without tamponade (Fig. 5A) and pericardial constriction (Fig. 5B) showed a convex or straight lateral border to the superior vena cava and right atrium.

The change in diameter of the superior vena cava from its minimal width at the right atrial junction to its maximal width below the azygos vein (caval compression ratio) ranged from 0.23 to 0.79 in Group 1 with tamponade and from 0.53 to 0.88 in Group 2 (Table II). The mean caval compression ratio (0.5 ± 0.05 standard error of the mean [SEM]) in the tamponade group differed significantly by Student's t test from that in the nontamponade group (0.74 ± 0.04 [SEM], $p = 0.001$).

The phasic narrowing ratio of the superior vena cava, measured only at the superior vena cava-right atrial junction, ranged from 0.34 to 0.85 for the tamponade group, and from 0.64 to 0.91 for the control group. The

FIGURE 2. Typical superior vena cavogram in cardiac tamponade demonstrating a gradual lateral concavity of the superior vena cava below the right pulmonary artery. Additional abnormalities include the flat shape of the free wall of the right atrium, inferior vena caval reflux, filling of the azygos vein (**arrow**), concavity of the anteroseptal wall of the right ventricle, superior displacement of the heart above the diaphragm, and increased separation of the lung from the right atrial cavity. Caval compression ratio = 0.52.

FIGURE 3. Variations in the shape of the superior vena cava during atrial systole in tamponade. **Left,** the superior vena cava (**arrows**) has a lateral step near the right atrial junction. Extrinsic compression is indicated by the small right atrial size, tricuspid stenosis, inferior vena caval reflux, and increased separation of the lung from the atrial cavity. Caval compression ratio = 0.46; phasic narrowing ratio = 0.73. **Right,** medial displacement of the superior vena cava (**arrows**) with a lateral step in atrial systole indicates tamponade, along with the less specific inferior vena caval reflux. The anteroseptal right ventricular wall is abnormally concave, compressed anteriorly by fluid. Caval compression ratio = 0.39; phasic narrowing ratio = 0.54.

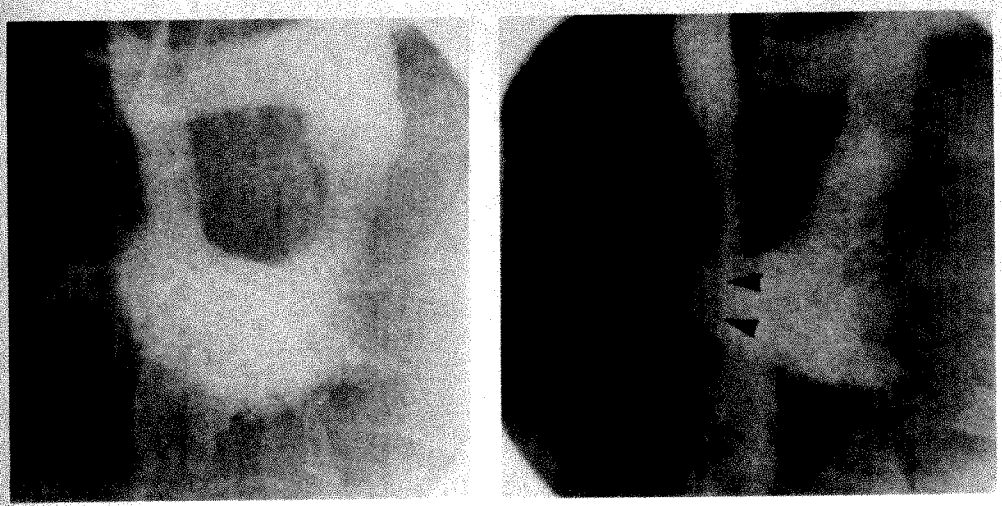

FIGURE 4. Dynamic change in the shape of the superior vena cava during **(left)** atrial diastole and **(right)** atrial systole in cardiac tamponade. The anterolateral wall of the right atrium remains convex **(arrow)** while the posterior wall segment is concave **(arrowheads)**.

mean phasic narrowing ratio also differed between the 2 groups, 0.66 ± 0.05 for tamponade versus 0.8 ± 0.04 (SEM) in the nontamponade group, $p < 0.04$.

Stepwise logistic regression revealed that the caval compression ratio was superior ($F = 15$) as a discriminator to the phasic narrowing ratio ($F = 5$). In fact, the final probability model produced by stepwise logistic regression rejected both the phasic narrowing ratio and the right atrial wall shape as not containing any significant additional discriminating power beyond that of the caval compression ratio. Using a cutpoint in predicted probability of tamponade versus other pericardial diseases of $p > 0.62$ (that is, predicted probability of tamponade >0.62 was judged a diagnosis of tamponade), the probability model which emerged from the logistic regression using the caval compression ratio had a sensitivity of 80% and a specificity of 90%.

Other radiologic signs of pericardial disease: Other radiologic signs of pericardial disease were present but not specific. In 9 of 10 patients in both Groups 1 and 2, reflux occurred down the inferior vena cava and frequently into the hepatic veins. This sign presumably reflects the high right atrial pressure. The right atrial wall in those patients with tamponade was concave in 7, straight in 1, and convex in 2. In the control group, the shape of the lateral right atrial wall was concave in 9 and straight in 1. An increased distance between the right atrial cavity and the right lung was present in all with tamponade and varied markedly in those in Group 2.

Similar abnormal changes in the configuration of the right atrial free wall were noted on 2-dimensional echocardiography. All 10 patients with tamponade had marked concavity of the right atrial free wall during atrial relaxation and ventricular isovolumic systole (Fig. 6). During subsequent atrial filling and ventricular ejection, the right atrial free wall resumed a normal convex configuration. In 3 patients 2-dimensional echocardiography was performed after pericardiocentesis. These studies demonstrated that the right atrial free wall resumed a normal configuration and was no longer inverted at any point during the cardiac cycle.

Discussion

This study suggests that the shape of the proximal superior vena cava can reliably distinguish cardiac tamponade from other pericardial diseases associated with abnormal right atrial hemodynamic function. This distinction could be made even though elevated right atrial pressures were present in both the group with tamponade (14 ± 3 mm Hg) and the control group (13 ± 6 mm Hg). Since all but 1 of our patients had a mean right atrial pressure of at least 10 mm Hg, these angiographic signs may not be present in patients with low pressure cardiac tamponade which can develop in the presence of hypovolemia. In the patient reported by

Superior vena caval angiograms in 2 patients whose right heart hemodynamic function indicated constriction. **Left,** straight free wall of the right atrium, inferior vena caval reflux, and decreased filling of the right ventricle. Caval compression ratio = 0.73; phasic narrowing ratio = 0.90. **Right,** slightly convex lateral wall of the cava and right atrium. Caval compression ratio = 0.75; phasic narrowing ratio = 0.86.

Antman et al,[26] low pressure cardiac tamponade was present with a mean right heart pressure of 8 mm Hg. The mean right atrial pressure of 13 mm Hg in our series almost certainly precluded dehydration.

The superior vena caval shape and the phasic narrowing ratio predict the presence of tamponade even when other types of pericardial disease are present. When pericardial effusion coexists with thickening of the visceral and parietal pericardium, clinical and hemodynamic signs may be confusing because varying degrees of tamponade or constriction, or both, may be present.[27] The difficulty in distinguishing the various pericardial entities appears to result from a lack of specificity in the usual hemodynamic[1,9,15,19,28] and angiographic[2,3,4,20,22,23] signs, along with the frequent coexistence of both (effusive-constrictive pericarditis). In contrast to these previous studies, the caval compression ratio of the superior vena cava has a sensitivity of 80% and a specificity of 90% when the ratio is 0.62 or less. The caval compression ratio achieved this degree of differentiation between patients with and without tamponade even though the control group was biased against this distinction because all but 3 patients in the control group had right atrial pressure greater than 10 mm Hg. Using the probability model developed by the stepwise logistic regression analysis, we identified those patients who would not have been correctly classified by a caval compression ratio of 0.62 or less (Table II). There were 2 false-negative diagnoses in Group 1 and 1 false-positive diagnosis in Group 2. All 3 of these patients had effusive-constrictive pericarditis with right atrial pressure not falling to normal values after pericardiocentesis.

Several factors could influence the shape of the right atrium and superior vena cava when tamponade is present: the amount and location of the pericardial fluid, the size of the heart, the phase of respiration and of the cardiac cycle, and the presence of any loculated fluid or adhesions.[6,14] The volume of this fluid increases in the inferior regions with inspiration as the diaphragm descends. The cardiac cycle itself causes a redistribution of fluid with more fluid collecting anteriorly and to the left in ventricular systole and laterally to the right in ventricular diastole. The change in the distribution of

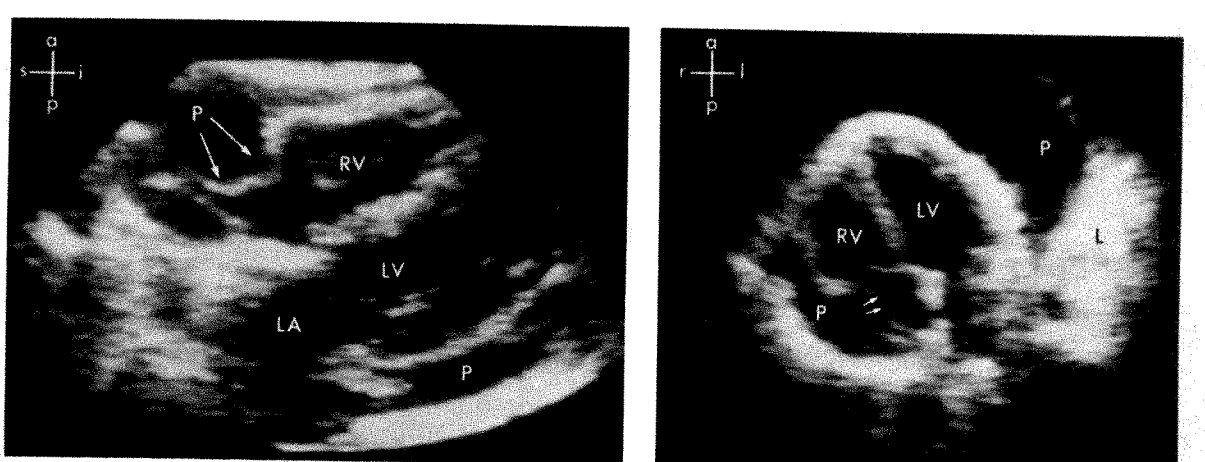

FIGURE 6. Left, 2-dimensional echocardiographic subcostal view of right atrial buckling (**arrows**) in cardiac tamponade. **Right,** apical 4-chamber view in a patient with lymphoma (L). The free wall of the right atrium is concave (**arrows**). a = anterior; l = left side; LV = left ventricle; P = pericardial fluid; p = posterior; r = right side; RV = right ventricle; LA = left atrium; s = superior; i = inferior.

pericardial fluid with the cardiac cycle offers an explanation of the concave or straight right atrial lateral border. This angiographic sign in our series usually was present in atrial systole but was quite variable in atrial diastole. A possible explanation is that the expansion of the right ventricle in diastole created a hydraulic increase in pressure, causing the right atrium to collapse its lateral wall inward. This mechanism is supported by our echocardiographic studies in patients with tamponade which demonstrate total reversal of the normal direction of curvature of the right atrial free wall after atrial systole. Since this type of motion cannot result from active muscular contraction, it must be caused by passive compression from without. Its temporal relation to maximal ventricular filling further suggests that the increased intrapericardial pressure expansion of one area of the heart must be accompanied by hydrodynamic compression of another area. Since the atria at end-atrial systole and early atrial diastole are the lowest pressure areas within the heart, it is to be expected that they would be most susceptible to deformity. The left atrium does not have a pericardial space adjacent to it, leaving the right atrium to suffer the greatest effects of this external compression.

The shape of the right atrial free wall in tamponade, as seen on the 2-dimensional echocardiogram, offers an explanation for the lack of sensitivity of the radiographic right atriogram. With angiography, the lateral wall of the right atrium may be convex, straight, or concave in the posteranterior projection when tamponade is present. In our 10 patients with tamponade who had echocardiograms, the right atrial wall was sharply concave and at times U-shaped. A portion of the right atrial wall always projected within the silhouette that would be cast by a radiographic study. The contrast medium in the lateral aspect of the right atrium then would obscure the medial invagination of the free wall. In Figure 4 the anterior right atrial wall is convex, while the posterior segment is concave, reflecting the buckle. If the right atrium were densely opacified, this posterior line would not be seen.

Various angiographic signs have been recognized for both effusive-constrictive and pure constrictive pericarditis.[3,4,20–23] Straightening of the right atrial contour and an increased width of the pericardium adjacent to the right atrium are present in most patients with pericardial disease. The lack of volume change during the last half of diastole in both ventricles is a hallmark of constrictive pericarditis, but this sign is usually absent when tachycardia is present. Angiographic analysis of left ventricular volume changes in patients with constrictive pericarditis have shown a faster than normal volume increase in early diastole.[28]

Since angiography entails a small but definite risk, the indications of superior vena cavography when tamponade is suspected must be tempered by the clinical situation, the expected gain in information, and the therapeutic options. When tamponade is obvious clinically and is confirmed by echocardiography, we perform pericardiocentesis without angiography. When the type of pericardial heart disease is not apparent after clinical examination and right heart catheterization, we utilize the configuration and motion of the superior vena cava and right atrium to differentiate patients whose dominant abnormality is cardiac tamponade from those who have other types of pericardial disease. Our preliminary observation on 2-dimensional echocardiography of buckling of the right atrial wall, along with the previous recognition of fluid loculation and intrapericardial abnormalities,[29] may allow noninvasive correlation with specific pericardial findings in the future.

Occlusive Thromboaortopathy (Takayasu's Disease) And Pregnancy

Clinical Course and Management of 33 Pregnancies and Deliveries

KAICHIRO ISHIKAWA, MD and SHUMPEI MATSUURA, MD

Twenty-seven Japanese patients with occlusive thromboaortopathy (Takayasu's disease) associated with 33 pregnancies and deliveries were followed up prospectively, from the prepregnant period. Inflammatory activity of the disease was apparently not enhanced by the pregnancy, but various cardiovascular-related events occurred in the perinatal period. During the intrapartum uterine contractions, marked elevation of systolic blood pressure was associated with 10 pregnancies, including 1 case of subsequent cerebral hemorrhage; this did not occur in 13 normal control gravidas. There were no maternal or neonatal deaths. The birth weight of 25 infants of 21 patients without complications or with a mild single complication of Takayasu's disease was 3,023 ± 442 g (mean ± standard deviation). The birth weight of 8 infants of 6 patients who had a severe single complication or multiple complications of the disease was 2,599 ± 394 g ($p < 0.05$). Of 83 pregnancies, the present 33 plus 50 other reported cases, there were no untoward events in two fifths. Three fifths had various problems, most of which were related to pressure elevation and heart failure, including intrapartum cerebral hemorrhage in 4. These data should assist in predicting the outcome of pregnancy and delivery in patients with Takayasu's disease.

Despite the tendency of occlusive thromboaortopathy (Takayasu's disease) to occur in women of the childbearing age, there is little information on the effect of pregnancy in these women or on the effects of the disease on pregnancy and its management. There are reports of 50 women with Takayasu's disease and 57 pregnancies,[1-38] including our previous reports of 7 pregnancies.[22,23] The great majority of reports, however, describe 1 or 2 cases and are short-term studies. From these studies, it is difficult to predict the incidence and type of complications and whether a pregnant woman with the disease will have an uncomplicated or complicated course.

Takayasu's disease is a chronic inflammatory arteriopathy of unknown origin.[39] The site of occurrence is the aorta or its main branches, or both; the pulmonary artery is often involved. The nature of the disease gives rise to 4 main complications: Takayasu's hypotensive ischemic retinopathy, secondary hypertension, aortic regurgitation, and aortic or arterial aneurysm.[40] The prognosis in patients with severe single or multiple complications is poorer than that in patients with only mild complications or without complications altogether.[41] Consequently, the problems related to pregnancy and delivery are superimposed on the established cardiovascular complications and inflammatory activity of the disease. Thus, a cardiologist is often consulted to evaluate the risks of pregnancy, labor, and delivery and the condition of fetus.

The clinical course of 33 pregnancies and deliveries in 27 Japanese women with Takayasu's disease and the follow-up studies are reported herein. The influence of pregnancy, labor, and delivery on the clinical course of the disease and the effects of the disease on pregnancy are analyzed. The pregnancies discussed herein, in addition to 50 other pregnancies in 46 patients with Takayasu's disease, are reviewed and the management is discussed.

Methods

Patient selection: During the 16 year period from April 1966 to January 1982, we treated 27 Japanese patients and a total of 33 pregnancies and deliveries, including 6 previously reported patients and 7 deliveries[22,23] (Table I). One pregnancy and the subsequent delivery was studied in 21 patients and 2 pregnancies were followed in 6 patients. The average age (± standard deviation) at the time of delivery in these 33 women was 28 ± 3 years. The average age at the time of onset of symptoms of Takayasu's disease and at the time of the diagnosis in the 27 patients was 19 ± 5 years and 23 ± 4 years, respectively. Of the 27 patients, 17 were admitted to the Third Department of Internal Medicine, Kyoto University, where the diagnosis of Takayasu's disease was established. These 17 women became pregnant during a follow-up period of 5.3 ± 3.7 years (mean ± standard deviation) after the diagnosis was established. In the remaining 10 patients, the diagnosis was confirmed after referral to our vascular outpatient clinic from other institutions.

From the Third Division, Department of Internal Medicine and Department of Obstetrics and Gynecology, Faculty of Medicine, Kyoto University, Kyoto, Japan. Manuscript received March 29, 1982; revised manuscript received June 9, 1982, accepted June 18, 1982.

* This case belonged to Group IIb: TR before pregnancy. † The case of left hemiparesis as sequelae of cerebral thrombosis at age 18.

AR = aortic regurgitation; BP = blood pressure; CHF = congestive heart failure; CPD = cephalopelvic disproportion; CS = Cesarean section; D = diuretic; FUO = fever of unknown origin; MP = multipara; PP= primipara; SH = secondary hypertension; TR = Takayasu's retinopathy.

In 24 of the 27 patients, angiography was performed; in the remaining 3, the diagnosis of Takayasu's disease was made clinically. The pulmonary circulation in 21 patients was studied using pulmonary arteriography, cardiac catheterization, and perfusion lung scanning in 10, and with perfusion lung scanning alone in 11.

Patient classification: To evaluate the disease status in detail, the following 3 factors were used: complications attributed to Takayasu's disease, sites of arterial lesions, and inflammatory activity of the disease as determined by the erythrocyte sedimentation rate.

Complications: The 27 patients were classified into 4 groups (Groups I, IIa, IIb, and III) according to the presence and severity of 4 complications attributed to Takayasu's disease at the time the diagnosis was established. The criteria for this classification were previously reported,[40] except for a slight modification of the criteria concerning severity of Takayasu's retinopathy.[41,42] As a rule, the severity of aortic regurgitation was assessed angiographically.[43] The aortographic grades of 3+ and 4+ were defined as severe aortic regurgitation. Retinal arterial pressure and blood pressure in the arms was measured with the women in the supine position. The prone position was used for pressure measurement in the thighs. During the third trimester, labor, and delivery, the pressure measurement in the thighs was usually performed with the patient in the supine position. During labor and vaginal delivery, analgesia and anesthesia were not given, except in a few cases.

All but 3 of 27 patients were reclassified clinically before the pregnancy or during the early period in the first trimester. As a result, 5 patients were improved: 4 from Group IIb to Group I or IIa, and 1 from Group IIa to I. On the other hand, aggravation was evident in 2 patients: 1 from Group I to IIa and 1 from Group I to IIb. Findings in the remaining 17 patients remained unchanged.

Sites of arterial lesions: According to the location of arterial lesions, the disease was anatomically classified into 3 types[44–46]: (1) aortic arch type, (2) descending aorta type, or (3) extensive type (combined aortic arch and descending aorta type). Of the 27 patients, 7 had aortic arch type disease and 20 had the extensive type at the time of the diagnosis. The descending aorta type was not detected in any patient.

Inflammatory activity: When erythrocyte sedimentation rate (Westergren) was consistently ≥20 mm/hour, inflammatory activity of Takayasu's disease was defined as the active stage, except during pregnancy and 6 weeks after delivery. Of 16 patients in the active stage at the time of diagnosis, 10 became inactive or the inflammatory activity was suppressed, and 6 remained unchanged before pregnancy. Eight patients in the inactive stage remained unchanged. In the remaining 3, the diagnosis of Takayasu's disease was first made during pregnancy.

Criteria for markedly elevated systolic pressure during intrapartum uterine contractions: By our definition, a markedly elevated systolic blood pressure during uterine contractions with bearing down efforts in the second stage of labor meant a maximum elevation of ≥70 mm Hg over the values between uterine contractions in the first stage of labor, or those before initiation of labor. In the first stage of labor, a markedly elevated systolic pressure during the height of a uterine contraction indicated a recurrent increase of ≥40 mm Hg. As a control group for the intrapartum pressure values, 13 healthy pregnant women were selected at random from patients hospitalized in our institution. These women had a normal antepartum course and a normal spontaneous labor at term with delivery of a living fetus; analgesia or anesthesia was not administered. Measurement of brachial blood pressure was performed consistently by 1 of the authors with the patient in the supine position. In the first stage of labor, blood pressure was measured when the cervix was dilated 4 to 8 cm.

Criteria for evaluating effects of pregnancy on the patient: Pregnancy was considered to have an unfavorable effect on patients with Takayasu's disease when Group I, IIa and IIb, or III progressed by 1 or more during pregnancy and the puerperium. A favorable effect was found when the classification improved by 1 or more groups. An occurrence of major events (Table I) also was considered an unfavorable effect. From the standpoint of inflammatory disease activity, the following were considered unfavorable: (1) an increase of ≥30 mm above the prepregnancy values of erythrocyte sedimentation rate per hour during the first half of the pregnancy and an increase of ≥60 mm in the second half; (2) an increase of 20 mm or more above the prepregnancy values over 6 weeks after delivery. A decrease of ≥20 mm under the prepregnancy values indicated a favorable effect.

Definition of preeclampsia, superimposed preeclampsia, and low birth weight: Preeclampsia and superimposed preeclampsia were defined according to the Committee on Terminology of the American College of Obstetricians and Gynecologists[47]: preeclampsia—development of gestational hypertension with proteinuria, edema, or both, after the 20th week of gestation; superimposed preeclampsia—occurrence of preeclampsia in a woman with antecedent hypertension. Criteria for the diagnosis of gestational hypertension were defined as a rise in systolic blood pressure of ≥30 mm Hg, or a rise in diastolic pressure of ≥15 mm Hg, or an absolute level of ≥140/90 on 2 occasions at least 6 hours apart. Low birth weight (a birth weight of 2,500 g or less) was defined according to the World Health Organization Expert Committee on Maternal and Child Health.[48]

Evaluation of pregnancy potential in the total population with the disease: During the 25 year period from 1957 to 1982, 90 patients admitted to the Third Department of Internal Medicine at Kyoto University were diagnosed as having Takayasu's disease. Of the 90 patients, 38 were selected for an evaluation of pregnancy potential in patients with Takayasu's disease, including 19 of the 27 patients in the present series. The remaining 52 patients were excluded from the study on pregnancy potential: 10 men, 18 unmarried women, 18 mothers of 2 or more children before the time of onset of symptoms of Takayasu's disease, and 6 married women using birth control methods but not birth control pills. (These 6 were excluded for a recurrent hemoptysis, a postoperative status of aortic bypass graft, a giant aneurysm of the ascending aorta (operative death), a continuance of corticosteroid therapy with a large daily dose, and economic difficulties [2].)

Statistical analysis: Statistical comparisons were made using the t test, the paired t test, and the chi-square method with the Yates correction for continuity.

Results

Classification and distribution of patients: The 27 patients were reclassified before pregnancy or during an early period in the first trimester of pregnancy. Combined Groups I and IIa comprised 21 patients (77.8%) and combined Groups IIb and III, 6 patients (22.2%). Of the 21 patients in whom pulmonary circulation was studied, 10 had involvement of the pulmonary artery.

Effect of pregnancy: The effect of pregnancy, labor, and delivery on the clinical course of Takayasu's disease is shown in Figure 1. Most of the unfavorable effects

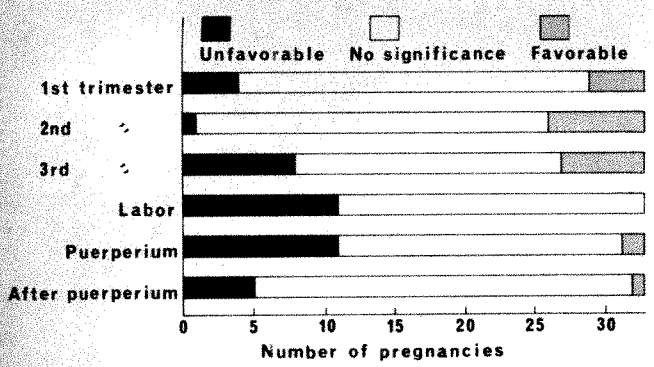

FIGURE 1. Effect of 33 pregnancies in 27 patients with occlusive thromboaortopathy. In 33 pregnancies, 4 (12.1%), 1 (3.0%), 8 (24.2%), 11 (33.3%), 11 (33.3%), and 5 (15.2%) had an unfavorable effect during the first trimester, second trimester, third trimester, labor, puerperium, and postpuerperium, respectively.

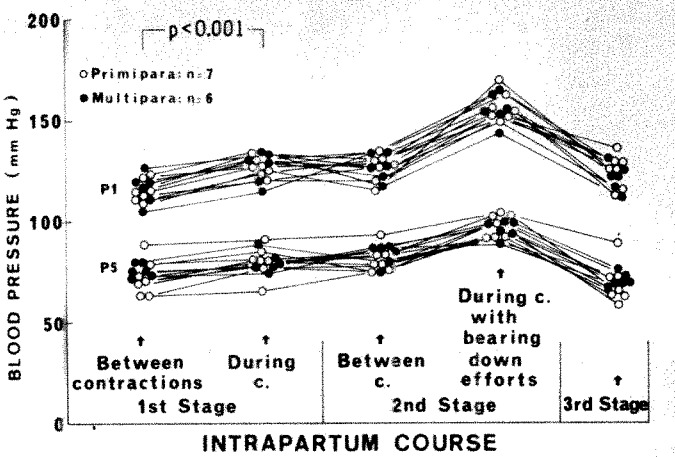

FIGURE 2. Blood pressure between and during uterine contractions in the intrapartum course in 13 healthy women. Measurements were obtained both during a complete uterine relaxation and during the height of a contraction. In each woman, the blood pressure value during each stage of labor and each phase of contraction was expressed as mean values obtained at 3 or more uterine contraction cycles. P1 = systolic pressure; P5 = diastolic pressure; p = probability.

were noted in the perinatal period. The second trimester of pregnancy was the most stable. There were no maternal deaths. Of the 33 pregnancies, 22 (66.7%) had an unfavorable effect and the remaining 11 (33.3%) were uneventful during the entire obstetric course. There was no significant difference in the incidence of an unfavorable effect during each period of the entire course between combined Groups I and IIa and combined Groups IIb and III (chi-square method). In all pregnancies, an inflammatory activity of the disease was not obviously affected by the pregnancy, even in a patient in the severe active stage (>100 mm/hour of erythrocyte sedimentation rate before pregnancy); in fact, there was a transient improvement in 5. There were no pattern changes in the group during pregnancy and the puerperium, except for 3 patients whose mild or moderate hypertension before pregnancy was transiently normalized. The grade 2/6 early diastolic murmur of aortic regurgitation before pregnancy became inaudible during the antepartum period in 1 patient. The same intensity of murmur became audible 3 weeks after delivery. The major events which developed during pregnancy, labor, and the puerperium are shown in Table I. There were differences in the character of the events in each period. In general, events due to cerebral ischemia occurred in the first trimester of pregnancy and the postpartum period, and cardiovascular events occurred in the perinatal period. An unfavorable effect remained in 5 patients after the puerperium, but permanent sequelae occurred in only 1 woman who had an intrapartum cerebral hemorrhage (Case I-17). Left temporal craniotomy and evacuation of the left intracerebral hematoma (lateral type) were successfully performed 20 hours after delivery.

In 13 healthy pregnant women whose average age (± standard deviation) was 29 ± 5 years, the response of blood pressure to uterine contractions during labor is shown in Figure 2. The value of blood pressure between and during uterine contractions in the first stage of labor was 116 ± 6/74 ± 7 mm Hg (mean ± standard deviation [SD]) and 127 ± 6/80 ± 7 mm Hg, respectively ($p < 0.001$). During uterine contractions with bearing down efforts in the second stage of labor, the average value of systolic pressure (± SD) was 156 ± 7 mm Hg. When the latter was calculated using the maximal value obtained in each gravida, it was 168 ± 9 mm Hg (range 150 to 186). There was no incidence of a rise in systolic pressure of ≥70 mm Hg in maximum over the pressure values between uterine contractions in the first stage of labor, in any patient. Regarding the blood pressure values obtained during labor in patients with Takayasu's disease, 10 pregnancies of the comparable 22 (4 in patients with arch type disease, 18 in patients with the extensive type) had markedly elevated systolic pressure during uterine contractions. In these 10 pregnancies, the response of blood pressure to uterine contractions during

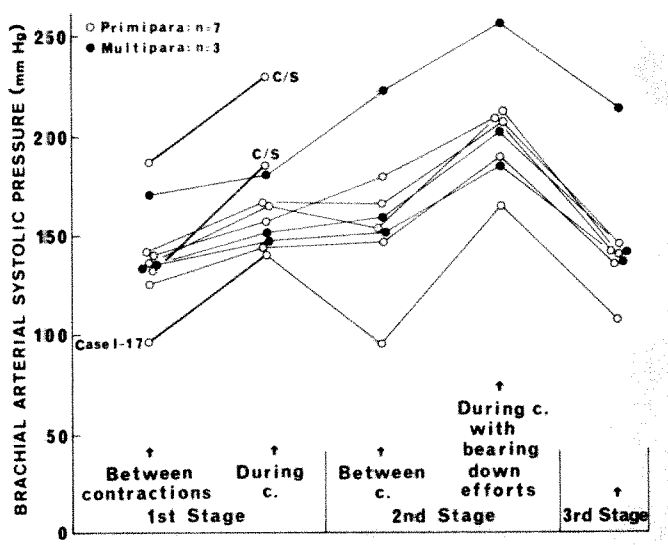

FIGURE 3. Brachial arterial systolic pressure in the intrapartum course in 10 pregnant women with Takayasu's disease and a marked pressure increment during uterine contractions. Blood pressure was expressed as mean values, as in Figure 2. CS = cesarean section.

labor is shown in Figure 3. The incidence of a marked increase in pressure in the 22 pregnancies was significantly greater than that (none) in the normal 13 pregnancies ($p < 0.025$). There was no significant difference in the average age at the time of delivery in the 2 groups (t test). The 10 patients with a marked pressure increase had the extensive type of disease and included 5 with preexisting secondary hypertension and 5 normotensive patients, not only before pregnancy but also during the antepartum period. Of the former, 1 had a superimposed preeclampsia in the third trimester; in 1 of the latter a cerebral hemorrhage occurred just before delivery (Fig. 4).

Treatment and management during pregnancy: During pregnancy, labor, delivery, and the puerperium, treatment included corticosteroids, anticoagulants, and symptomatic therapy for which antihypertensive agents, digitalis, and antibiotics were frequently used. Nonsteroidal anti-inflammatory agents were rarely prescribed. In 5 of the 27 patients, small doses (5 to 12.5 mg/day) of prednisolone, which the patients were taking at the time of conception, were continued throughout pregnancy, except for 1 patient who stopped taking prednisolone during pregnancy and in whom the inflammatory activity was increased after the puerperium. In another patient in the severe active stage before pregnancy, corticosteroid therapy with an initial daily dose of 50 mg of prednisolone was begun 14 weeks after delivery. Among 4 pregnant women receiving oral anticoagulant therapy (anisindione), 1 had macrohematuria in the third trimester and another had a postpartum hemorrhage. In 4 patients and 5 pregnancies, hospitalization was prescribed during the period from 23 to 36 weeks' gestation.

Follow-up after delivery: The 27 patients were followed up prospectively for observation periods of 5.9 ± 4.3 years (mean ± SD) from the time after the delivery to January 1982. Of the 27, 1 was lost to follow-up after 6 months and 1 died from a cerebrovascular accident 6 years after delivery. The remaining 25 patients were living as of January 1982.

Effect of disease on pregnancy: fetal and neonatal outcome: Of the 33 pregnancies, 30 ended at full term, namely, between 37 and 41 completed weeks of gestation. In the remaining 3, 2 ended at 36 weeks' gestation and 1 ended at 42 weeks' gestation. The average time of gestation (± SD) was 39.0 ± 1.5 weeks. Of 45 pregnancies during the period from onset of symptoms of Takayasu's disease to the present successful delivery in the 27 patients, 2 patients had pregnancy which ended in spontaneous abortion at 10 or 11 weeks' gestation. One other patient had a history of 2 preterm stillbirths (30 and 33 weeks) and 2 spontaneous abortions (both 13 weeks). There were no therapeutic abortions. No neonatal death or congenital anomaly occurred in the 33 infants. The average birth weight (± SD) of the 33 was 2,920 ± 463 g; 6 of the 33 (18.2%) were low birth weight but full term, except 1 (36 weeks). The birth weight of 25 infants of 21 patients in combined Groups I and IIa and that of 8 infants of 6 patients in combined Groups IIb and III was 3,023 ± 442 g (mean ± SD) and 2,599 ± 394 g, respectively ($p < 0.05$). Regarding gestational age of the infants, there was no significant difference between the 2 combined groups. Of the 33 infants or children, 32 were living as of January 1982, with an average age (± SD) of 5.9 ± 4.6 years. (One child was lost to follow-up 6 months after birth.)

Method of delivery: Twelve of the 33 deliveries (36.4%) were normal vaginal deliveries. Vacuum extraction was performed in 10 instances (30.3%) to expedite the second stage of labor because of fetal distress in 2, markedly elevated systolic pressure during uterine contractions with bearing-down efforts in 5, and antecedent hypertension in 3. Forceps were used in 1 (3.0%). In the remaining 10 deliveries (30.3%), cesarean section was performed for obstetric indications in 6 and for nonobstetric indications in 4. The latter included markedly elevated systolic pressure during intrapartum uterine contractions in 2 patients (Cases I-8 and I-13), superimposed preeclampsia in 1 (Case I-11), and extremely severe aortic arch type with unobtainable blood pressure in either arm in 1 (Case I-47) (Table I).

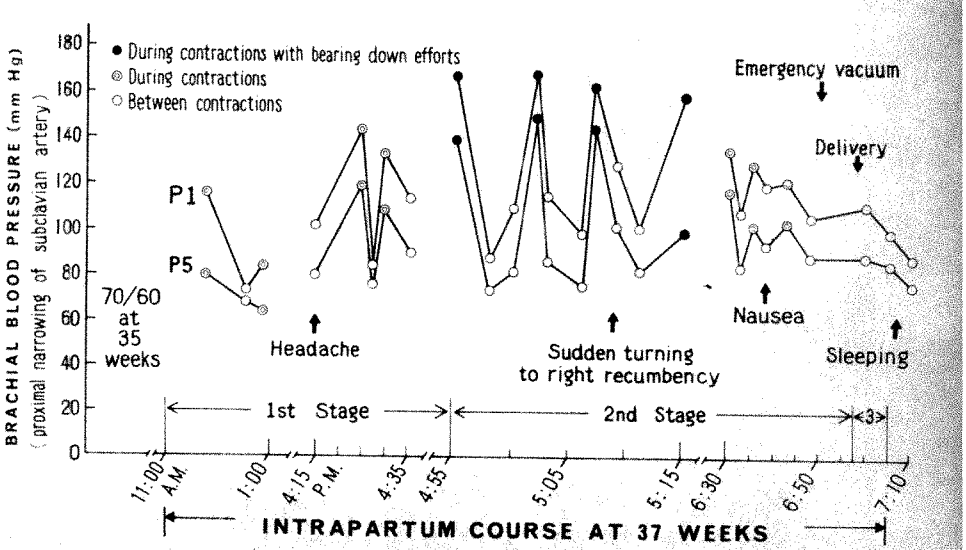

FIGURE 4. Intrapartum time course and right brachial blood pressure with narrowing of the ipsilateral subclavian artery at age 28 years in Patient I-17, in whom cerebral hemorrhage occurred in the second stage of labor. The actual systemic blood pressure was probably more elevated during uterine contractions, compared with values obtained in the right brachial artery. P1 = systolic pressure; P5 = diastolic pressure.

Pregnancy potential: Of the 38 patients with Takayasu's disease selected for evaluation of pregnancy potential, 30 (78.9%) were delivered of a live infant less than 3 years after the period filling the requirements of both occurrence of the basic disease and pregnancy. Five patients (13.2%) were delivered of 1 infant during the period from 3.3 to 6.5 years and the remaining 3 (7.9%) did not become pregnant, even in the absence of birth control practices, except for 1 patient who had 2 abortions. Table I summarizes the results of 33 pregnancies in the 27 patients.

Discussion

Effect of pregnancy on the patient: In this series, we found that the underlying disease activity, as reflected by the erythrocyte sedimentation rate, was not acutely affected by the pregnancy, regardless of an active or inactive stage before the pregnancy. In contrast, various cardiovascular events developed during pregnancy, labor, and the puerperium. A search of the world literature revealed 57 pregnancies in 52 patients with Takayasu's disease, most of which were reported by obstetricians.[1–38] Our evaluation of the effect of pregnancy, labor, and delivery on the disease was made according to the criteria described in the section on methods. Of the present 33 pregnancies and of the previously reported 50 (excluding our previously reported 7[22,23]), 51 (61.4%) had an unfavorable effect, including 4 deaths (4.8%); the remaining 32 (38.6%) were uneventful. Of 83 pregnancies, 11 (13.3%), 10 (12.0%), 31 (37.3%), and 23 (27.7%) had an unfavorable effect during the first, second, and third trimester and labor, respectively. The effect was unfavorable during the puerperium in 30 of 81 (37.0%). However, the unfavorable effect continued beyond the puerperium in only 5 pregnancies (15.2%) in the present series.

Of the maternal events, those related to elevation of blood pressure (regardless of the presence or absence of hypertension before pregnancy) and heart failure were the most frequent. These events usually were prominent in the perinatal period and were attributed to (1) heart failure and cerebrovascular accidents as the usual major factors related to death in nonpregnant patients with Takayasu's disease,[40,41] (2) the imposition of an increased cardiac load in the perinatal period on the underlying nature of the disease,[49–56] and (3) concomitant and extremely rapid changes in the cardiovascular system,[57–61] including fluctuations of blood pressure during the intrapartum and the subsequent course.

Intrapartum blood pressure and cerebral hemorrhage: In general, there is a paucity of data regarding the response of blood pressure to second stage contractions with bearing-down efforts.[58–61] Winner and Romney,[60] using invasive methods, reported increments of systolic pressure above resting levels from 15 to as high as 75 mm Hg during second stage contractions with expulsive efforts in normal gravidas. Their results, in which the maternal posture at the time of the measurements was not given, were similar to our data—an increase of up to 28 to 64 mm Hg, obtained in normal gravidas who were in the supine position (Fig. 2). In our pregnant patients with Takayasu's disease, the incidence of an abnormal response of systolic pressure to intrapartum uterine contractions, particularly to second stage contractions with bearing-down efforts, was significantly greater than in the normal control gravidas. The marked increase in pressure was not found in patients with the arch type of disease but in those with the extensive type. Therefore, such susceptibility of blood pressure to the marked elevation under these conditions may be partly related not only to the baroreceptor dysfunction of the carotid sinuses and the reduced windkessel effect of the involved aorta,[62,63] but also to a narrowing effect of the descending aorta.

Intracerebral hemorrhage during labor in patients with Takayasu's disease occurred in 4 patients, including 3 reported by Takeshita et al,[30] Miyakoshi et al,[34] and Takashina et al[35] and 1 of our patients (Case I-17). These 3 patients died. The 4 patients had the following characteristics in common: (1) extensive and severe occlusion, narrowing, or both of the main branches arising from the arch of the aorta, (2) marked increase in blood pressure in the first stage of labor, except for 1 patient in whom pressure measurement in any extremity could not be obtained, (3) presence of headache or nausea as a prodromal symptom, (4) occurrence of bleeding before delivery of the infant (at the first stage of labor in the 3 previously reported cases and at the second stage in our case), and (5) a history predisposing to classification into Group IIb or III in Takayasu's disease during the prepregnant course. In our 9 ptients with an intrapartum marked elevation of systolic pressure but no cerebral hemorrhage, cervical arterial lesions were not so severe as the lesions related to retinal arterial microaneurysms. Thus, the intrapartum cerebral hemorrhage in patients with Takayasu's disease may be due in part to a combination of severity of intrapartum elevation of central blood pressure and of antecedent cerebral ischemia. In general, intracerebral hemorrhage during labor rarely occurred even in pregnant patients with cerebral arterial aneurysm or angioma,[64] congenital coarctation of the aorta,[65] and chronic hypertension or superimposed preeclampsia.[66] Takayasu's disease is one of the diseases associated with intrapartum cerebral hemorrhage.

Evaluation of the disease as related to the risks of pregnancy: There was no significant difference in incidence of an unfavorable effect of pregnancy on the basic disease between patients in combined Groups I and IIa and those in combined Groups IIb and III. However, these results may be due in part to the influence of elective cesarean section, prophylactic management, or both, particularly in patients in Group IIb (Cases I-13 and I-47). Patients with the extensive type and retinal microaneurysms or a history before pregnancy may have intrapartum cerebral hemorrhage. According to previous reports,[41] among patients in Group IIb or III, those with a severe disability had the poorest prognosis. Therefore pregnancy in these patients should be avoided, interrupted, or continued under conditions of hospitalization. In the present series, there was only 1 such severe case (Case I-13). During pregnancy, aortic regurgitation[67] and high blood

pressure[68,69] in some patients with Takayasu's disease may be underestimated or overlooked. Variations of blood pressure responses during pregnancy, apart from the blood pressure response during labor in prepregnant hypertensive patients with Takayasu's disease, were similar to those in patients with essential hypertension.[68]

Medical, obstetric, and anesthetic therapy or management: Medical treatment of pregnant patients with Takayasu's disease may not differ essentially from that of the nonpregnant patients, except for obstetric considerations. Oral anticoagulant therapy should be postponed because of maternal and fetal hazards[70] until the puerperium, when nursing mothers given warfarin may safely breast-feed their infants.[71] Regarding maternal corticosteroid therapy, it has been suggested that the fetus is seldom affected by the therapy,[72,73] although some investigators[74,75] have reported adverse effects. In our series, there were no obvious maternal and fetal risks arising from the use of prednisolone in 5 patients prescribed a small, daily dose. Of the 5, 1 patient discontinued the drug during pregnancy and the inflammatory activity of the disease was considerably increased after the puerperium, as compared with before the pregnancy. Therefore, the small daily dose of prednisolone ingested before pregnancy should be continued during pregnancy. We recommend that initiation of a large daily dose of prednisolone during pregnancy be postponed until the postpuerperal period. Except for a patient with fulminant progression of arterial occlusive changes, commencement of this therapy after the puerperium may be effective, even in a patient with very high inflammatory activity of the disease (Case O-7). Prophylactic antibiotics should be used at the time of delivery in all patients, particularly in patients on corticosteroid therapy, in order to prevent bacterial endocarditis or septicemia not only because of aortic regurgitation but also because of narrowing of the aorta and its main branches. Septicemia occurred in 1 patient after cesarean section (Case I-54). Oral contraceptives should be avoided, as there may be adverse effects on patients with Takayasu's disease.[76] In this series, no patient was taking oral contraceptives.

For management of blood pressure, clinical evaluations of pressure values obtained in the extremities are most important not only to the physician but also to the obstetrician and anesthesiologist because (1) the pressure measurement in the arteries distal to the site of narrowing of the aorta and its main branches does not always give the "actual" blood pressure; (2) pressure measurement in the legs is not always practical in the second stage of labor; and (3) a slight decrease in blood pressure in patients with extensive and severe occlusive lesions of main cervical arteries frequently leads to syncopal attack or to severe cerebral ischemia. Elective cesarean section for nonobstetric indications may be recommended for the following patients: (1) in Groups IIb and III, particularly in those with severe Takayasu's retinopathy in the extensive type of the disease, if they have markedly elevated systolic blood pressure (defined earlier) during uterine contractions in the first stage of labor, (2) in Groups IIb and III if pressure measurement cannot be obtained in either arm, (3) in Groups I and IIa if they have markedly elevated systolic pressure with symptoms in the first stage of labor, despite medical treatment. In vaginal delivery, the second stage of labor can be shortened using a vacuum extractor or forceps. Intravenous injection of uterotonic agents, particularly ergonovine maleate,[77] should be avoided or at least closely monitored because of occurrence of increased dyspnea or cyanosis in some patients with Takayasu's disease.[1,17,21] Anesthetic considerations in this disease have been well summarized.[78]

Fetal outcome and fertility: In the present series, there was no increase in fetal mortality and no particular tendency toward spontaneous abortion in patients with Takayasu's disease. However, the incidence of low birth weight (2,500 g or less) was 18.2% (6 of the 33 infants), and the value may be higher than the 9.0% incidence in Japan in 1952.[79] The average birth weight of infants of the patients in combined Groups IIb and III was significantly lower than that of infants of the patients in combined Groups I and IIa. Among the 8 pregnancies in the former combined groups, 6 belonged to Group IIb and had signs of severe Takayasu's retinopathy. Therefore, the intrauterine growth retardation of the fetus in patients with Takayasu's disease may be related in part to severity of heart failure[80,81] and hypertension,[82] and cerebral ischemia in which Takayasu's ischemic retinopathy may be representative. As described in the section of pregnancy potential, fertility is apparently not affected by the disease, although it was suggested that a patient with this disease often has an anovulatory menstruation due to hormonal imbalance.[83]

Implications: The basic disease was not obviously affected by the pregnancy. However, the cardiovascular complications attributed to Takayasu's disease were transiently modified in many and often seriously enhanced in some patients. To prevent expected events or further enhancement of events already present, the following are important: (1) a prepregnant evaluation of the individual's basic disease, as related to risks and safety of pregnancy, (2) careful management during the periods when untoward events may occur, (3) planning the mode of delivery from both obstetric and nonobstetric indications, and (4) the intrapartum and anesthetic considerations with special reference to the measurement and management of blood pressure. Close cooperation among the cardiologist, obstetrician, and anesthesiologist is indispensable to successful pregnancy, labor, delivery, and puerperium in the woman with heart disease,[84] particularly Takayasu's disease.

Left Ventricular End-Systolic Stress-Shortening and Stress-Length Relations in Humans

Normal Values and Sensitivity to Inotropic State

KENNETH M. BOROW, MD, LAURENCE H. GREEN, MD, WILLIAM GROSSMAN, MD, and EUGENE BRAUNWALD, MD

Experimental studies suggest that the extent of left ventricular (LV) fiber shortening is determined by both the wall stress at end-systole and the contractile state. To evaluate the relation between these variables assessed noninvasively, 26 normal subjects were studied by M-mode echocardiography, phonocardiography, and indirect carotid pulse tracings during infusion of methoxamine to alter load (in all 26 subjects) and infusion of dobutamine (in 10 subjects) to increase contractility. End-systolic pressure was estimated from the incisura of a calibrated carotid pulse tracing. LV end-systolic dimension and wall thickness, and percent internal dimension shortening were determined by echocardiography, and end-systolic meridional wall stress was calculated. The relation between end-systolic stress and shortening was inversely linear ($r = -0.83$) for 130 control points. Dobutamine infusion resulted in a higher percent fractional shortening for any end-systolic stress; all 43 stress-shortening points were more than 2 standard deviations above the mean for the regression line. The relation between stress and dimension for the control points showed wider scatter than between stress and shortening ($r = 0.56$). However, in individual patients dobutamine always shifted the stress-dimension lines to the right, as compared with the baseline position resulting in a smaller end-systolic dimension for any end-systolic wall stress.

Thus, LV end-systolic wall stress and percent fractional shortening are inversely and linearly related and their relation can be accurately assessed by noninvasive methods. The end-systolic stress-shortening relation is highly sensitive, while the end-systolic stress-dimension relation is less sensitive to alterations in LV inotropic state.

The assessment of intrinsic LV contractile state, particularly by noninvasive means, remains a complex and controversial problem. The most commonly used clinical measurements of LV contractility are the ejection fraction, the percent fractional shortening, and the rate of change of LV wall thickening or dimension during systole. These ejection phase indexes, however, are affected importantly by the heart's loading condition and vary directly with end-diastolic fiber length (preload) and inversely with afterload.[1-4] Their clinical utility is limited by a wide range of normal values and the inability to distinguish between the mechanical effects of abnormal loading conditions and intrinsic depression in an inotropic state.

Several alternative methods of assessing LV contractile state have recently been studied. It has been known for many years that the left ventricular isovolumetric force-length relation, which is dependent on contractile state, describes the maximal force attainable for any degree of myocardial stretch.[5,6] Experimental studies performed in isolated canine hearts have dem-

onstrated that LV force-length relations obtained either isovolumetrically or at the end of ejection are virtually identical.[4,7–9] For any LV contractile state, shortening ceases when the active force-length relation coincides with a point on the isovolumetric force-length line. At this point, the LV wall force equals the maximal force that muscle length can sustain. In addition, for a given end-diastolic volume and contractile state, the end-systolic pressure-volume relation determines the extent of LV muscle shortening irrespective of the peak systolic pressure.[10] LV shortening ends when a unique relation between instantaneous systolic force and muscle length occurs. This relation is sensitive to contractile state, but is independent of end-diastolic fiber length as well as early or peak LV ejection forces. From these studies of basic cardiovascular physiology, the relation between LV end-systolic muscle length, force opposing shortening (wall stress), and extent of shortening appear potentially useful indexes of contractile state which incorporate afterload conditions.[11]

Recently, we reported a safe, easily performed noninvasive method of assessing LV function at end-systole.[12,13] In the present study, we used this method to evaluate end-systolic stress-shortening and stress-length relations in humans with emphasis on their normal relations as well as sensitivity to alteration in contractile state. This was accomplished by studying the response of the left ventricle to the alteration of loading conditions by the infusion of a pure alpha-adrenergic agonist without direct cardiac effect (methoxamine)[14,15] and to changes in the contractile state by infusion of a positive inotropic agent (dobutamine).[16,17]

Methods

Study population: The study population consisted of 26 healthy subjects (11 male, 15 female) ranging in age from 8 to 41 years, all of whom had no history of cardiovascular disease, were taking no cardioactive medications, and had normal physical examination, electrocardiogram, and intracardiac anatomy by M-mode echocardiography.

Experimental protocol: An Irex Continutrace Model 101 and ultrasound module with a 2.25 or 3.5 MHz transducer was used for the M-mode echocardiographic recordings. An external microphone was placed at the right upper sternal border area for phonocardiographic recordings. Peak systolic and diastolic blood pressure measurements were made with the Dinamap™ 845 Vital Signs Monitor (Critikon, Tampa, Florida). In a recently reported study,[18] we found that this device can estimate central aortic pressure accurately over a wide range of systolic (98 to 177 mm Hg) and diastolic (41 to 97 mm Hg) pressures, independent of the patient's cardiac index, systemic vascular resistance, left ventricular ejection fraction, heart rate, or body surface area. The mean percent error (± standard deviation) between simultaneously measured central and Dinamap pressures was 1 ± 4 mm Hg for systolic and 2 ± 4 mm Hg for diastolic readings.

Subjects were premedicated with intravenous atropine, 0.01 mg/kg, to abolish reflex cardiac slowing. Each subject underwent simultaneous recordings of systolic and diastolic blood pressures, echocardiography of the left ventricle, phonocardiography, indirect carotid pulse tracing, and electrocardiography under baseline conditions. Blood pressure was then elevated by the intravenous infusion of methoxamine at 25 μg/kg/min (maximal infusion rate 1 mg/min). The LV response to the pressor challenge was assessed by repeating the recordings every 1 to 2 minutes during the infusion. When peak systolic pressure had increased by 30 to 60 mm Hg above the resting values, the methoxamine infusion was discontinued. The peak pressor effect lasted 2 to 5 minutes. When systolic blood pressure had fallen by 15 to 20 mm Hg below the peak value, an intravenous infusion of 5 μg/kg/min of dobutamine hydrochloride was begun in 10 of the subjects. As the pressor effect of methoxamine further decreased with metabolism of the drug, the LV response to the positive inotropic intervention was recorded over a range of afterload conditions. In order to avoid the complicating effects of changes in heart rate, data points were excluded when the latter varied by more than 10 beats/min from baseline.

The echocardiographic LV end-diastolic internal dimension and end-diastolic wall thickness were measured at the onset of the Q-wave of the electrocardiogram while the end-systolic internal dimension and wall thickness were measured synchronously with the first high frequency component of the second heart sound. The measurements for end-diastolic and end-systolic dimensions and wall thicknesses were taken as the mean values for 5 cardiac cycles. LV percent fractional shortening (%ΔD) was calculated as follows: $\%\Delta D = (D_{ED} - D_{ES})/D_{ED}$, where D_{ED} is the end-diastolic and D_{ES} the end-systolic dimension. LV mid-wall end-diastolic and end-systolic dimensions were calculated as the internal dimension plus wall thickness at end-diastole and the internal dimension plus wall thickness at end-systole, respectively. This assumes that the septal and posterior wall surfaces of the left ventricle are of equal thickness. LV mid-wall percent fractional shortening ($\%\Delta D_{mw}$) was calculated as follows: $\%\Delta D_{mw} = (D_{ED_{mw}} - D_{ES_{mw}})/D_{ED_{mw}}$, where $D_{ED_{mw}}$ is the end-diastolic and $D_{ES_{mw}}$ the end-systolic mid-wall dimension. LV end-systolic and end-diastolic volumes were estimated from echocardiographic internal dimensions utilizing the method of Teichholz et al,[19] which assumes that the visualized portion of the left ventricle is representative of global ventricular function, an assumption previously shown valid in normal subjects in the absence of ventricular synergy. LV stroke volume was calculated as the end-diastolic minus end-systolic volumes; LV output was calculated as the product of stroke volume and heart rate. The accuracy of this method of estimating LV stroke volume in patients with symmetrical or nearly symmetrical contraction patterns is comparable to that obtained with single plane LV cineangiography.[20]

The carotid pulse tracings were calibrated using the automated blood pressure monitor device after the method of Stefadouros et al,[21] with systolic pressure assigned to the peak and diastolic pressure assigned to the nadir of the tracing. End-systolic pressure was estimated by linear interpolation to the height of the incisura. This method has been validated previously over a wide range of end-systolic pressures (84 to 160 mm Hg) in our cardiac catheterization laboratory against an intraarterial standard. The mean difference between direct and indirect pressure measurements was 3 mm Hg with a standard deviation of the difference of 4 mm Hg and a correlation coefficient of 0.97.[22]

LV meridional wall stress at end-systole was calculated using the angiographically validated method described by Grossman et al[23,24]: $\sigma_{ES} = [(P_{ES})(D_{ES})(1.35)]/[(4)(h_{ES})(1 + h_{ES}/D_{ES})]$, where σ_{ES} is end-systolic wall stress in g/cm^2; P_{ES} is end-systolic pressure in mm Hg; D_{ES} and h_{ES} are end-systolic dimension and wall thickness in cm; and 1.35 is the factor to convert pressure from mm Hg to g/cm^2.

TABLE I Hemodynamic Response to the Afterload Challenge

	Baseline	Peak Pressor Effect	p Value
Heart rate (beats/min)	90 ± 21	91 ± 22	NS
P_{PS} (mm Hg)	115 ± 7	163 ± 13	<0.001
P_D (mm Hg)	71 ± 10	103 ± 9	<0.001
P_{ES} (mm Hg)	94 ± 8	137 ± 10	<0.001
D_{ES} (cm)	3.10 ± 0.40	3.50 ± 0.40	<0.001
D_{ED} (cm)	4.65 ± 0.55	4.95 ± 0.55	<0.001
$\%\Delta D$	33.7 ± 2.2	30.0 ± 2.6	<0.001
$\%\Delta D_{mw}$	18.9 ± 1.9	18.4 ± 2.1	NS
SV (ml)	62 ± 12	64 ± 14	NS
CO (liters/min)	5.6 ± 1.3	5.8 ± 1.4	NS
h_{ES} (cm)	1.40 ± 0.20	1.25 ± 0.20	<0.001
σ_{ES} (g/cm^2)	50 ± 18	95 ± 30	<0.001

CO = cardiac output; D_{ES} = end-systolic dimension; D_{ED} = end-diastolic dimension; $\%\Delta D$ = percent internal dimension fractional shortening; $\%\Delta D_{mw}$ = percent mid-wall fractional shortening; h_{ES} = end-systolic wall thickness; P_{PS} = peak systolic pressure; P_D = diastolic pressure; P_{ES} = end-systolic pressure; σ_{ES} = end-systolic meridional wall stress; SV = stroke volume.

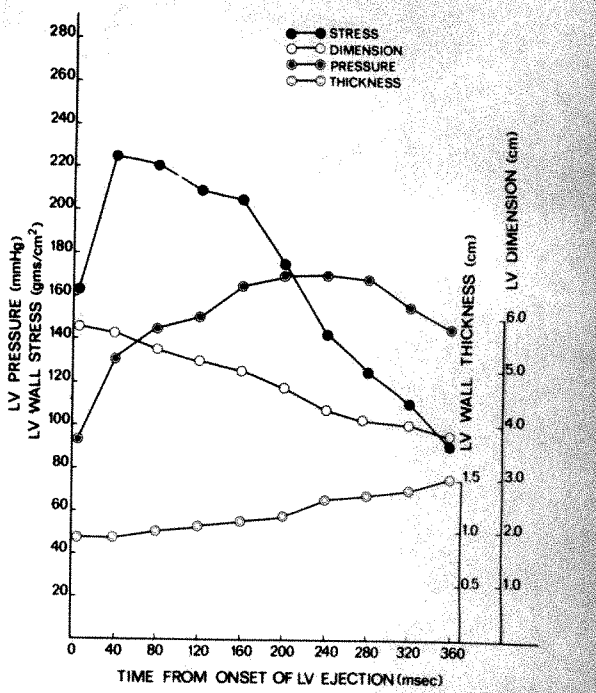

FIGURE 1. LV meridional wall stress calculated throughout ventricular ejection in a representative subject from simultaneous measurements of LV pressure, dimension, and wall thickness. Wall stress peaked early in ventricular systole and then declined throughout the remainder of the ejection period. The relatively long LV ejection time (370 ms) was due to the subject's slow heart rate (R-R interval 1330 ms).

All subjects were studied using a protocol approved by the Human Studies Committee of the Brigham and Women's Hospital and of the Children's Hospital Medical Center.

Data analysis: Simple linear regression (least squares method) was used to fit each subject's data to a stress-shortening ($\%\Delta D = m[\sigma_{ES}] + b$) and stress-length ($D_{ES} = m[\sigma_{ES}] + b$) equation, where m = the slope and b = the y intercept. The extrapolated LV end-systolic wall stress when end-systolic dimension is zero is equal to $-b/m$. In the 10 subjects who received the dobutamine infusion, a comparison of the LV response under control and increased inotropic conditions was performed using Student's t test for paired data. A p value <0.05 was taken as indicative of statistical significance. Unless otherwise noted, the data are presented as the mean ±1 standard deviation.

The 130 control end-systolic stress-shortening, stress–mid-wall shortening, and stress-dimension points were pooled and linear regression equations with 95% confidence limits (±2 standard deviations) determined for each relation. Any dobutamine points outside these limits were considered statistically different from the control population.

Results

LV hemodynamics: Table I summarizes the hemodynamic response to the afterload challenge for the 26 normal subjects. LV end-systolic dimension, end-systolic stress, and end-diastolic dimension varied directly

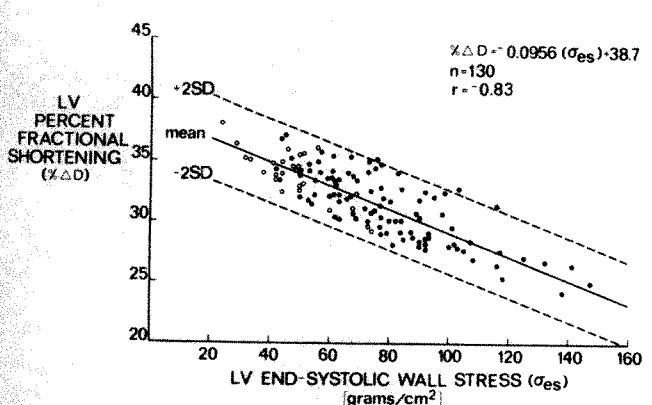

FIGURE 2. Relation between LV end-systolic wall stress (σ_{es}) and percent fractional shortening ($\%\Delta D$) for the 130 control points obtained at rest (**open circles**) or during methoxamine infusion (**closed circles**). LV σ_{es} and $\%\Delta D$ are inversely and linearly related over a wide range of values.

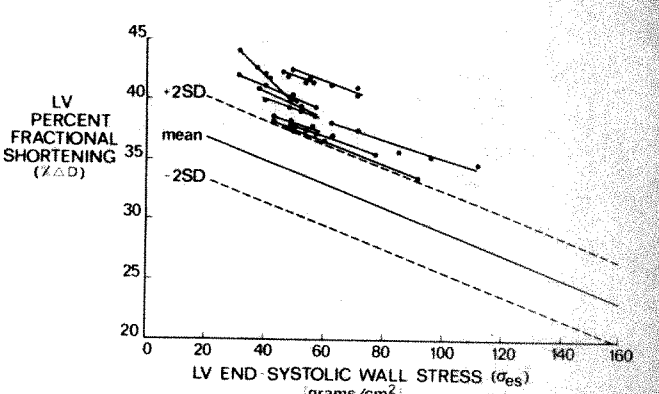

FIGURE 3. Plot of the LV end-systolic wall stress (σ_{es})-shortening ($\%\Delta D$) relation, showing its sensitivity to inotropic state. All of the σ_{es}-$\%\Delta D$ points obtained during the dobutamine infusion were greater than 2 standard deviations above the mean value for the regression line generated from the 130 control points.

C = control; D = dobutamine; D_{ES} = end-systolic dimension (cm); D_{ED} = end-diastolic dimension (cm); % ΔD = percent fractional shortening; h_{ES} = end-systolic wall thickness (cm); HR = heart rate (beats/min); P_S = peak aortic systolic pressure (mm Hg); P_D = aortic diastolic pressure (mm Hg); P_{ES} = end-systolic pressure (mm Hg); σ_{ES} = end-systolic meridional wall stress.

whereas end-systolic wall thickness and percent fractional shortening varied inversely with increased ventricular pressure. Heart rate, stroke volume, and cardiac output remained unchanged.

The time courses for the changes in LV pressure, dimension, wall thickness, and meridional wall stress during ejection for a representative subject are shown in Figure 1. LV systolic wall stress peaked early after the onset of ejection, at a time when changes in LV dimension and wall thickness were minimal and LV pressure was increasing. As systole progressed, ventricular dimension decreased and wall thickness increased, resulting in a progressive decrease in wall stress despite little change in pressure.

The hemodynamic response of each of the 10 subjects given dobutamine infusions are shown in Table II. Data are matched for end-systolic pressure. With the dobutamine infusion, heart rate increased by 13% (87 ± 23 versus 98 ± 23 beats/min; $p < 0.05$). For any end-systolic pressure, end-systolic dimension was smaller during the dobutamine infusion than in the absence of the drug. End-diastolic dimension was not significantly affected by the change in inotropic state. The net result was a

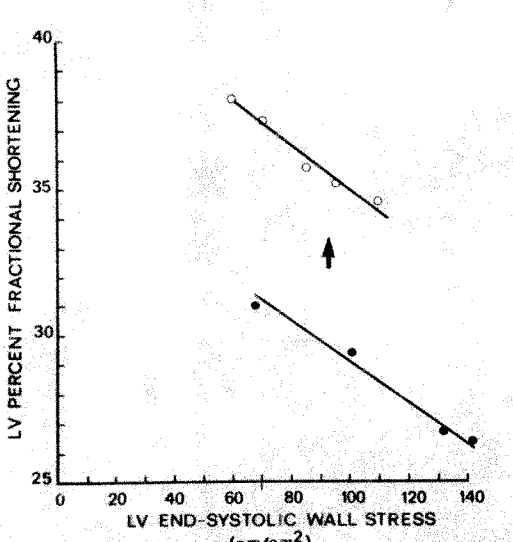

FIGURE 4. Comparison of the LV end-systolic wall stress-shortening lines joining points at different afterloads for control (**closed circles**) and increased (**open circles**) contractile states in a representative subject. With the dobutamine infusion, the % ΔD is higher for any σ_{es}.

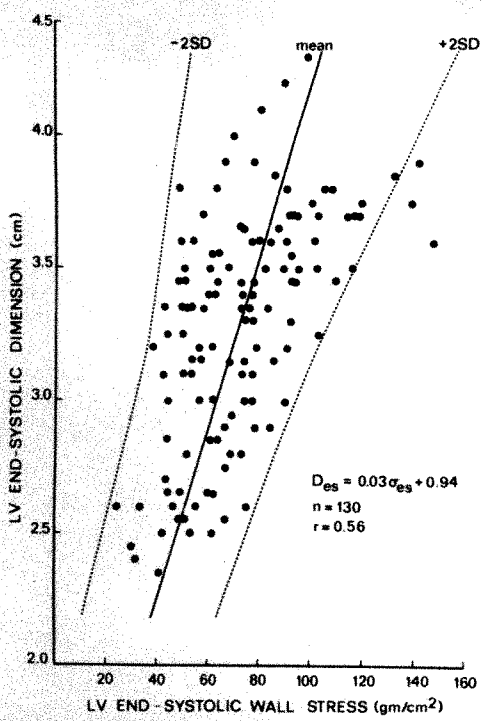

FIGURE 5. Relation between LV end-systolic wall stress (σ_{es}) and dimension (D_{es}) for the 130 control points. Although these variables are linearly related, there is wide scatter, with a correlation coefficient of +0.56.

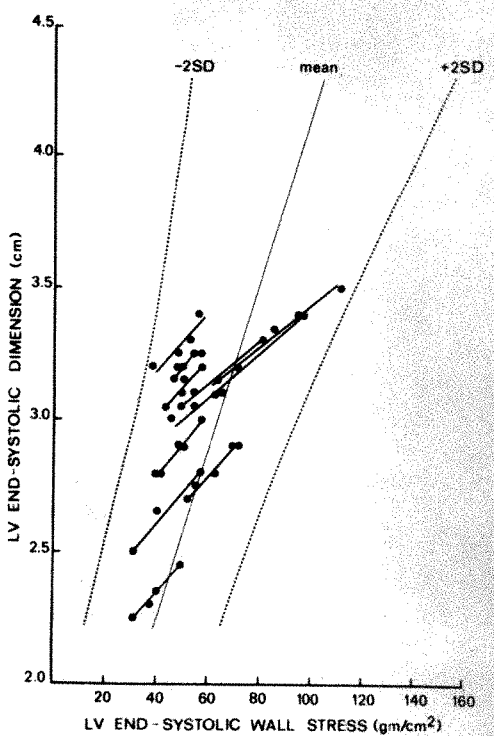

FIGURE 6. Plot of the LV end-systolic wall stress (σ_{es})-dimension (D_{es}) relation. There is extensive overlap between σ_{es}-D_{es} points obtained during dobutamine infusion and the mean ±2 standard deviations for the regression line generated from the 130 control points.

21% mean increase in stroke volume (66 ± 10 to 80 ± 16 ml; $p < 0.01$) and a 38% increase in cardiac output (5.6 ± 1.4 to 7.7 ± 2.2 liters/min; $p < 0.01$).

LV end-systolic stress-shortening relation: When the 130 control points obtained from all 26 patients were pooled, the relation between LV end-systolic stress and shortening was inversely linear with a correlation coefficient of −0.83 (Fig. 2). Using linear regression, percent fractional shortening was best predicted by the following equation: $\%\Delta D = -0.0956(\sigma_{ES}) + 38.7$. With dobutamine infusion, all 43 stress-shortening points were more than 2 standard deviations above the mean values for the regression line (Fig. 3). In each individual case, dobutamine infusion resulted in a higher percent shortening for any end-systolic stress (Table II, Fig. 4). This was demonstrated by the increase in the extrapolated value for shortening when end-systolic stress was zero, from 36.6 ± 2.2 in the absence of dobutamine to 45.5 ± 3.2 ($p < 0.01$) in its presence. The slope of the stress-shortening line did not change consistently with dobutamine, increasing in 8 cases and decreasing in 2.

For individual subjects, an increase in end-systolic stress resulted in small increases in LV mid-wall end-systolic dimension and mid-wall end-diastolic dimension. There was a poor correlation between mid-wall percent fractional shortening and end-systolic wall stress ($r = 0.15$). Sixteen of the 43 dobutamine points fell within the 95% confidence limits for this relation.

LV end-systolic wall stress-dimension relation: The relation between LV end-systolic stress and dimension for the 130 control points showed wide scatter with a correlation coefficient of 0.56 (Fig. 5). Using linear regression, end-systolic dimension was best predicted by the following equation: $D_{ES} = 0.03(\sigma_{ES}) + 0.94$, where D_{ES} is end-systolic dimension and σ_{ES} is end-systolic wall stress. Unlike the situation with the stress-shortening relation, the 43 stress-dimension points obtained during the dobutamine infusion fell within the range of the 130 pooled control points (Fig. 6). When the stress-dimension relation was analyzed for individual subjects, the curves were linear under control ($r \geq 0.91$) and increased inotropic states ($r \geq 0.92$). During the dobutamine infusion, the lines joining stress-dimension points at different afterloads were uniformly shifted to the right, resulting in smaller values of end-systolic dimension for any end-systolic stress. This is illustrated for a representative subject in Figure 7. For the 10 subjects who received dobutamine, the extrapolated end-systolic dimension value when stress was zero was consistently smaller with the positive inotropic intervention (2.8 ± 0.1 versus 2.4 ± 0.3; $p < 0.05$).

When each subject was used as his own control, the relative position, but not the slope, of the stress-dimension relation was sensitive to inotropic state. The relation between wall stress and chamber dimension changed throughout ventricular ejection (Fig. 8). Nei-

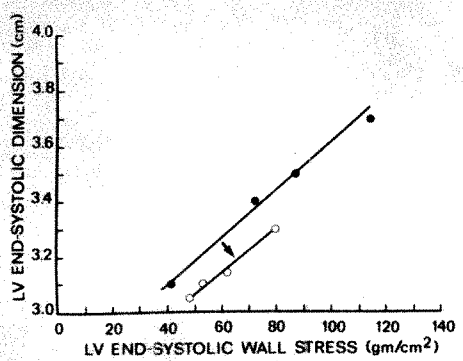

FIGURE 7. Comparison of the LV end-systolic wall stress-dimension lines joining points at different afterloads for control (**closed circles**) and increased (**open circles**) inotropic states in a representative subject. The end-systolic dimension was smaller during dobutamine infusion than under control conditions, despite comparable values for end-systolic wall stress.

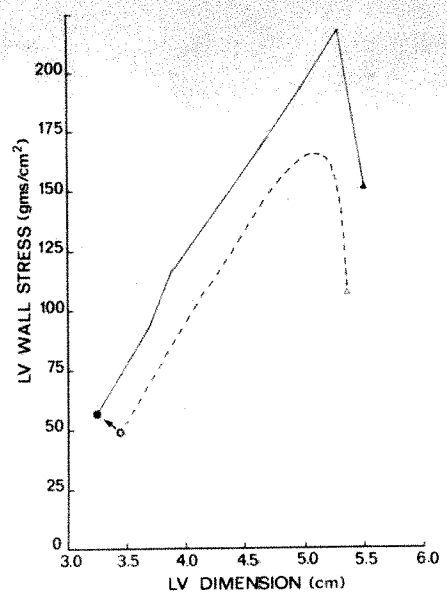

FIGURE 8. Comparison of the LV wall stress (σ)-dimension (D) plot for control (**dashed lines**) and increased inotropic (**solid line**) conditions in a representative subject. Neither the σ-D relation at onset of ejection (**triangles**) nor its course during ventricular shortening was able to distinguish between different inotropic states. LV ventricular end-systolic dimension (**circles**) was smaller during dobutamine infusion than under control conditions despite comparable values for end-systolic wall stress.

ther the stress-dimension relation in early systole nor its course during ventricular ejection was able to distinguish between different inotropic states. However, changes in contractility affected the position of the end-systolic stress-length relation.

Discussion

Methodologic considerations: Our study analyzed multiple points in each subject under both control and altered inotropic conditions in an effort to study LV function at end-systole. Rather than extrapolating conclusions from data generated by a single or at most 2 postextrasystolic potentiated beats, as has been the usual practice,[11,22,25] we analyzed the significance of position, slope, and axis intercept for the end-systolic stress-shortening and stress-dimension relations over a wide range of afterload conditions. This was accomplished using a safe, easily performed experimental design that requires minimal patient cooperation.

Certain potential limitations to this study should be noted. First, we used meridional wall stress rather than circumferential wall stress as a measure of LV afterload at end-systole. LV meridional stress, which is dependent only on ventricular intracavitary pressure, wall thickness, and diameter in the equatorial plane, can be calculated accurately using noninvasive techniques.[24] Although absolute values for meridional stress are lower than absolute values for circumferential stress because of differences in the radii of curvature in meridional and circumferential planes,[26] numerous studies have demonstrated that both variables are related to ventricular performance.[23,26,27]

Second, left ventricular percent fractional shortening is dependent on preload, afterload, and contractile state. In our study, contractility was assessed during primary alterations in LV afterload. Since preload has relatively little effect on the extent of ventricular shortening in patients without volume overload,[28] the relation between LV extent of shortening and force resisting shortening at end-systole (that is, wall stress), should reflect intrinsic contractile state. The possibility that an "afterload mismatch" occurred resulting in a depressed fractional shortening value out of proportion to end-systolic stress is unlikely since there was no limit to preload reserve as demonstrated by maintenance of a constant LV stroke volume despite increases in afterload.[4,29]

Third, the use of M-mode echocardiography in determining representative LV minor axis dimensions assumes symmetrical wall motion. While this assumption may be supported in normal subjects as well as in patients with valvular and diffuse myopathic diseases, this technique may be inaccurate in patients with coronary artery disease in whom regional wall motion may

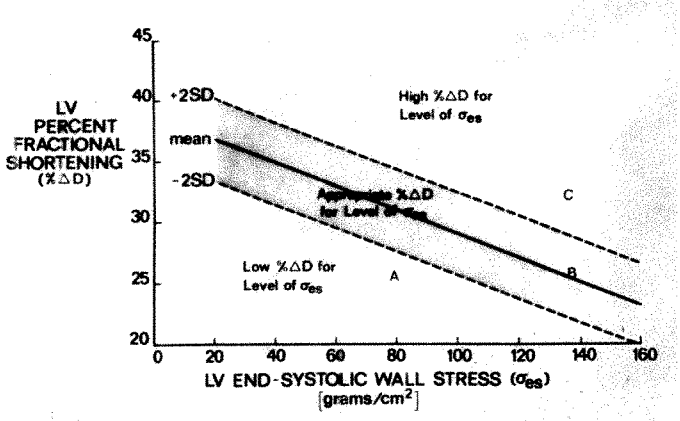

FIGURE 9. Diagram of the LV end-systolic wall stress (σ_{es})-shortening (% ΔD) relation. This relation may be useful in distinguishing depressed myocardial shortening due to excessive afterload (point B) from intrinsic contractile abnormality (point A). Hypercontractile states would be characterized by a higher than predicted % ΔD for any σ_{es} (point C versus point B).

not be representative of global LV performance. Two-dimensional echocardiography may be helpful in determining how any given diameter determined by M-mode echocardiography reflects the performance of the ventricle as a whole. The reproducibility of echocardiographic measurements of LV dimension is important to the validity of our results. We attempted to minimize this potential problem by recording all measurements over a short period (<30 minutes), using 1 technician, keeping the patient and transducer positions stationary throughout the study, and employing the guidelines for echocardiographic measurements recommended by the American Society for Echocardiography.[30] A recent study using a similar approach found no statistically significant intra- or interobserver variation in M-mode echocardiographic measurement of end-systolic or end-diastolic dimension in normal subjects studied serially over a 4 week period.[31]

Fourth, we assumed that ventricular contractile state remained uniform under increased afterloading conditions. Although methoxamine has no direct cardiac inotropic effect,[14,15] the possibility of sympathetically mediated reflex changes in contractility cannot be excluded. However, this possibility appears unlikely, since heart rate remained relatively constant as afterload was altered. In addition, sympathetically mediated reflexes have, at most, a small contribution to the resting inotropic state in normal human subjects.[32,33] This was confirmed recently by Crawford et al,[34] who studied the cardiac effects of an acute pressure load in normal subjects after administration of atropine and atropine plus propranolol. No significant difference in ventricular performance was observed before or during beta-blockade therapy, suggesting that the sympathetic nervous system has minimal influence on the heart during an acute afterload challenge.

Finally, we used the pressure at end-ejection to approximate true end-systolic pressure. While the aortic incisural pressure may slightly underestimate LV pressure at the instant of maximal ventricular active contraction, the difference between these 2 points is probably small.[35] Although some investigators have used *peak* systolic pressure to approximate true end-systolic pressure, we recently showed that the end-systolic pressure-dimension relation using incisural rather than peak systolic pressure is more sensitive to alterations in ventricular contractility, especially in patients with high cardiac output states.[12]

Implications: The primary findings of this study are that LV end-systolic wall stress and percent fractional shortening are inversely and linearly related, that this relation is highly sensitive to alterations in inotropic state, and that this relation can be accurately assessed by noninvasive methods. The LV end-systolic stress-dimension relation, while less sensitive in assessing the baseline LV inotropic state, nevertheless can be used to detect whether an intervention alters this state.

As may be noted in Figure 1, LV wall stress is normally highest early during ventricular systole and then declines throughout the remainder of the ejection period. In the normal heart, the decline in ventricular dimension and the increase in wall thickness that occur after aortic valve opening are responsible for this decline, which occurs despite the increase in intracavitary pressure during most of the ejection period.[23] LV wall stress at end-systole represents the force (afterload) which the shortened myocardial fibers cannot overcome. At this point, the active and isovolumetric force-length relations become equal, the active state ends, and ventricular shortening is terminated.[7,8] Our results indicate that the greater the load opposing shortening at end-systole, the smaller the extent of shortening. The significance of this interaction should be emphasized. As shown in Figure 2, a fractional shortening of 30% would be well within the normal range if end-systolic stress were 80 g/cm^2, but abnormally depressed if end-systolic stress were 40 g/cm^2. Thus, for the percent fractional shortening (or any other ejection phase index of LV performance) to reflect the intrinsic contractile state accurately, it must be defined in terms of the force at the termination of ejection. This study presents the range of values for the end-systolic stress-shortening relation in normal human subjects. It is of interest that mid-wall percent fractional shortening did not show a similar inverse correlation with increasing end-systolic wall stress, as was seen with internal dimension percent fractional shortening. This probably reflects the fact that mid-wall percent fractional shortening is not equivalent to mid-wall fiber shortening, since wall thickness (used in the calculation of mid-wall percent fractional shortening) changes markedly from end-diastole to end-systole. In contrast, internal dimension percent fractional shortening probably does reflect accurately the extent of myocardial fiber shortening.

The findings with the infusion of dobutamine, a beta-adrenergic agonist, illustrate how the end-systolic stress-shortening relation reflects changes in contractile state. For any end-systolic stress, the extent of myocardial fiber shortening was greater with the positive inotropic intervention than under control conditions (Fig. 3). The results of the dobutamine infusion also illustrate the concept of LV systolic reserve capacity. In each case, the dobutamine infusion resulted in a smaller end-systolic dimension for any end-systolic pressure despite a relatively constant end-diastolic dimension. This resulted in a rightward shift of the end-systolic stress-dimension relation as well as increases in LV percent fractional shortening and stroke volume.

The end-systolic stress-shortening plot for normal subjects obtained over a wide range of afterload conditions may be used in patients with reduced ejection phase indexes of LV performance to distinguish reduced myocardial shortening due to excessive afterload from depressed myocardial contractility (Fig. 9). Since force is expressed as end-systolic wall stress, which takes into account both LV chamber size and wall thickness, it should be possible to compare stress-shortening and stress-dimension relations in patients of different sizes and ages. In patients at risk for LV dysfunction, such as those with systemic hypertension and cardiomyopathy, a normal fractional shortening at a low end-sys-

tolic stress may represent a subtle preclinical abnormality in LV inotropic state not evident from other cardiac studies. This method may be of value in following asymptomatic patients with valvular heart disease, in whom deterioration of myocardial contractility often precedes the development of symptoms, and may point to the desirability of early surgical intervention. The applicability of this approach in patients with LV outflow tract obstruction needs to be investigated. Finally, this noninvasive technique may be useful in assessing the effects of potentially cardiotoxic drugs such as Adriamycin® on LV contractility,[36] and in assessing the effects on contractile state of drugs having purported positive inotropic effects, such as orally active sympathomimetic agents.

Acknowledgment: We thank Alexander Neumann, Lesia Stanchak, Priscilla Peters, and Mary Beth Giffune for their technical assistance; Joanne Miccile, Adele Slatko, and Emily Flynn for assistance in preparation of this manuscript; and Thomas Smith, MD, for review of the manuscript.

Your patients deserve the best ECG analysis they can get.

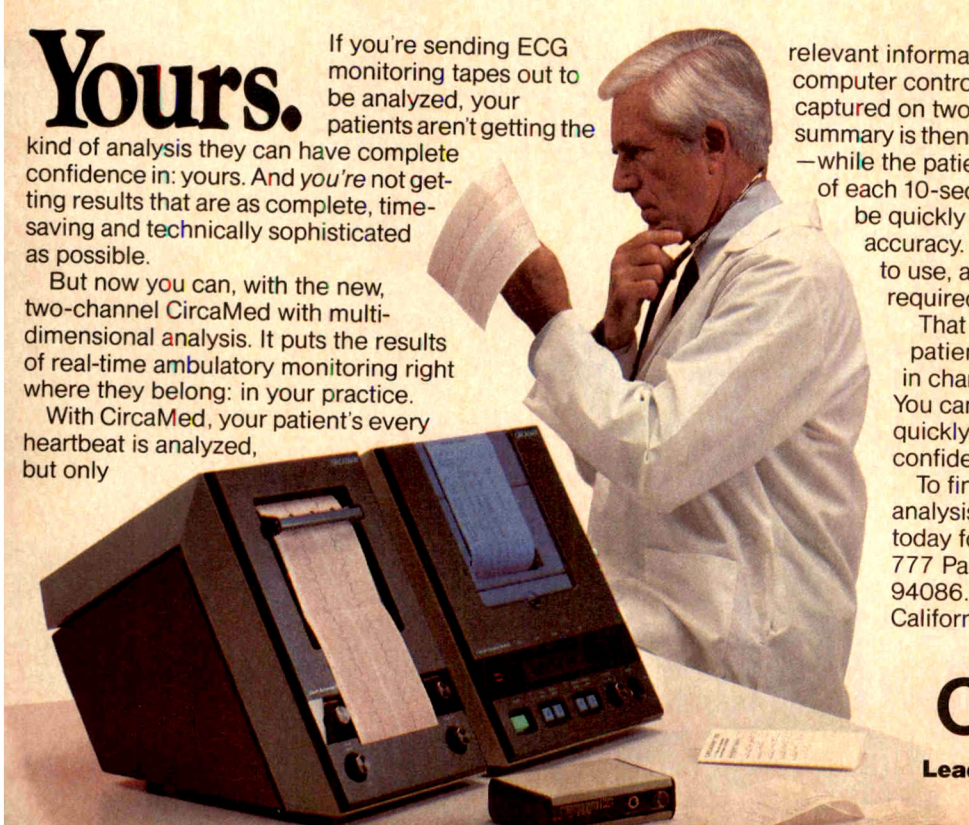
Yours. If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.

That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.



CIRCADIAN

Leaders in real-time ECG analysis.

ARRHYTHMIAS
Cardiovascular well-being often begins with Inderal®
(PROPRANOLOL HCl)
Inderal®
(propranolol hydrochloride)
10 mg
100 Tablets
Ayerst
AYERST LABORATORIES INC.
NEW YORK, N.Y. 10017

No agent offers a better risk/benefit profile in arrhythmias than INDERAL (propranolol HCl). INDERAL works to reduce heart rate and contractility, lengthen A-V conduction time, and suppress automaticity[1]—helping to restore the heart rate to normal in many patients with a wide variety of arrhythmias.

Consider INDERAL for arrhythmias early—to restore cardiovascular well-being as soon as possible.

Please see Brief Summary of Prescribing Information on the following page.

INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.

INDERAL®
(PROPRANOLOL HCl)

To restore cardiovascular well-being.

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

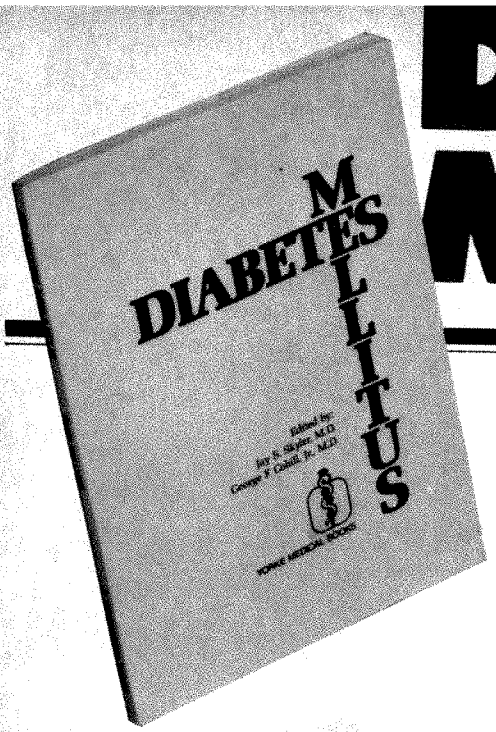
DIABETES MELLITUS



From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- The causes of diabetic inheritance
- Immune factors of diabetes
- Mechanisms of diabetes (The culmination of 50 years of research)
- Autoimmunity
- New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- New developments in the treatment of diabetes
- Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- Pharmacology of oral hypoglycemics
- Use of insulin infusion devices
- Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

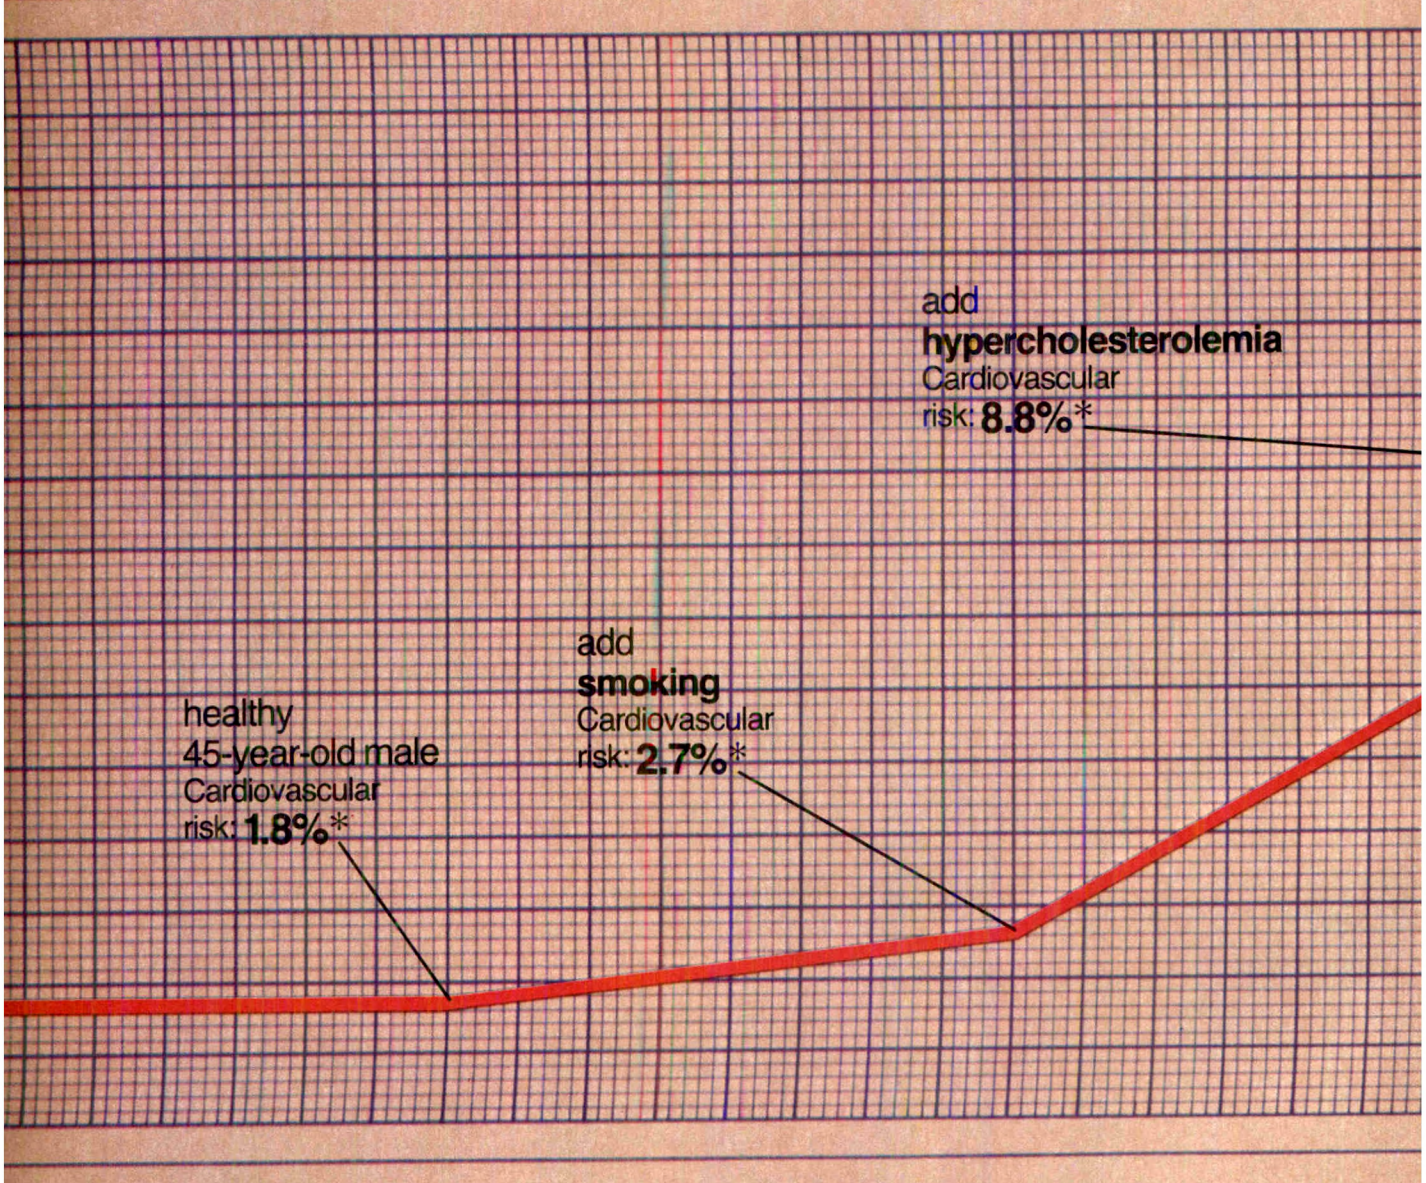
AB1

In hypertensive patients:

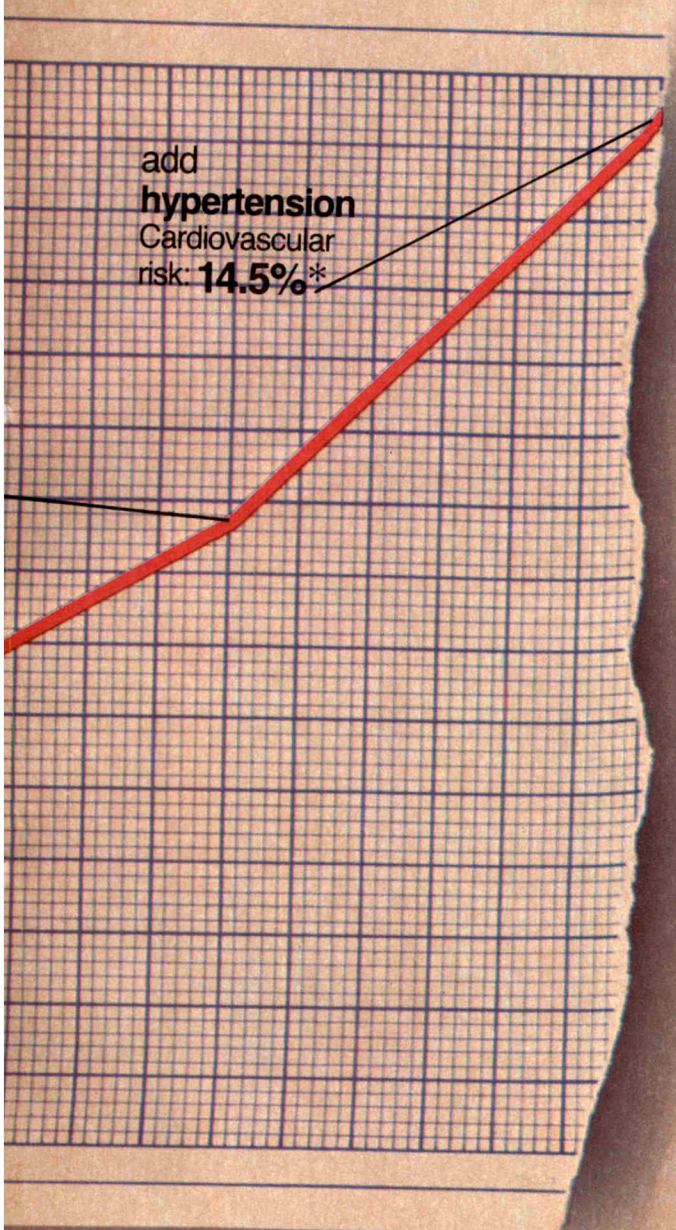


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) B.I.D. Dosage Convenience

Capsules 1 mg, 2 mg, 5 mg

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.
Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.
ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
Initial Dose: 1 mg two or three times a day (See Warnings.)
Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).
More detailed information available on request.

CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

William C. Roberts, M.D.
Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.

Dean T. Mason, M.D.
Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California

Mary Allen Engle, M.D.
Stavros S. Nierchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure...a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCL2

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)
(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

☐ Please bill my ☐ VISA ☐ MasterCard (same return privilege)

From today's research to tomorrow's frontiers . . . our titles cover the scope of cardiology.

THE ROLE OF SALT IN CARDIOVASCULAR HYPERTENSION

Edited by MELVIN J. FREGLY and MORLEY R. KARE

The mechanisms by which sodium may contribute to the development of high blood pressure in man and experimental animals are explored in this volume. Chapters discuss the ingestion of sodium, its content in foods, the internal factors that influence the appetite for salt, the physiological factors that regulate sodium loss in the body, and the interactions of sodium at the cellular level. Timely in view of the recent Food and Drug Administration proposal for labeling the sodium content of processed food, the book presents a discussion by an industry representative and an F.D.A. representative on the need for regulation and its impact on the industry.

1982, 496 pp., $39.50 ISBN: 0-12-267280-3

CELLULAR BIOLOGY OF THE HEART

Edited by H. E. MORGAN

The fifth US/USSR Symposium on Myocardial Metabolism held at Hershey, Pennsylvania in June 1981 is the basis for this collection of reviews. Chapters report on recent advances important for understanding those factors that regulate mechanical performance and the mechanisms of ischemic damage. Extensive tables and illustrations support the reviews. This volume demonstrates a fruitful international collaboration between leading scientists of the two countries and sets goals and directions for future research.

This book is a supplement to the *Journal of Cellular Cardiology* and is available free of charge to subscribers. Non-subscribers may purchase the book either through their bookseller or direct from Academic Press Inc.

1982, 160 pp., $18.00 ISBN: 0-12-506960-x

CARDIAC ELECTROPHYSIOLOGY TODAY

Proceedings of the International Symposium on Cardiac Electrophysiology held in Ferrara from April 28 to May 1, 1981.

Edited by ANTONIO MASONI and PAOLO ALBONI

This instructive volume thoroughly describes many aspects of cardiac arrhythmias, particularly from an electrophysiological viewpoint. It discusses in detail sinus dysfunctions, ventricular and supraventricular tachycardias, and intraventricular conduction disturbances, and reports on their histological, physiological, diagnostic, and therapeutic aspects.

1983, in preparation ISBN: 0-12-478150-0

TYPE A BEHAVIOR PATTERN

A MODEL FOR RESEARCH AND PRACTICE

VIRGINIA ANN PRICE, Ph.D.

With foreword by MEYER FRIEDMAN, M.D.

- What are the integrating principles or concepts of Type A behavior, and how do they relate to the observable behaviors associated with Type A?
- How is the Type A pattern learned?
- What accounts for the apparent persistence of Type A behavior throughout adult life, despite its obvious risks?
- What physiological processes may provide the link between type A behavior and coronary heart disease?

This book addresses these questions along with many others. It presents a practical, conceptual model of this coronary risk factor and integrates and clarifies the extensive body of research on the Type A concept.

1982, 320 pp., about $26.50 ISBN: 0-12-564680-1

CARDIOVASCULAR REVIEW 1983

GERALD C. TIMMIS, M.D., DOUGLAS C. WESTVEER, M.D., JAMES STEWART, M.D., RENATO G. RAMOS, M.D., ANDREW M. HAUSER, M.D., SEYMOUR GORDON, M.D., V. GANGADHARA, M.D., and RUDOLPH DRESSENDORFER, Ph.D.

FROM THE PREFACE: *Cardiovascular Review 1983* . . . assimilate(s) most of the clinically germane English-speaking cardiologic literature in as concise and timely a format as possible. Thus, this textual compendium of individual reports represents as current a summary of cardiologic thinking as the publishing process will allow. With 1625 references having been added to the 1982 edition, bringing the total to almost 7000, the Review constitutes not only as ready and comprehensive an updated reference as is probably available, but also a bibliographic resource.

1983, in preparation ISBN: 0-12-691340-4

Also Available From Academic Press . . .

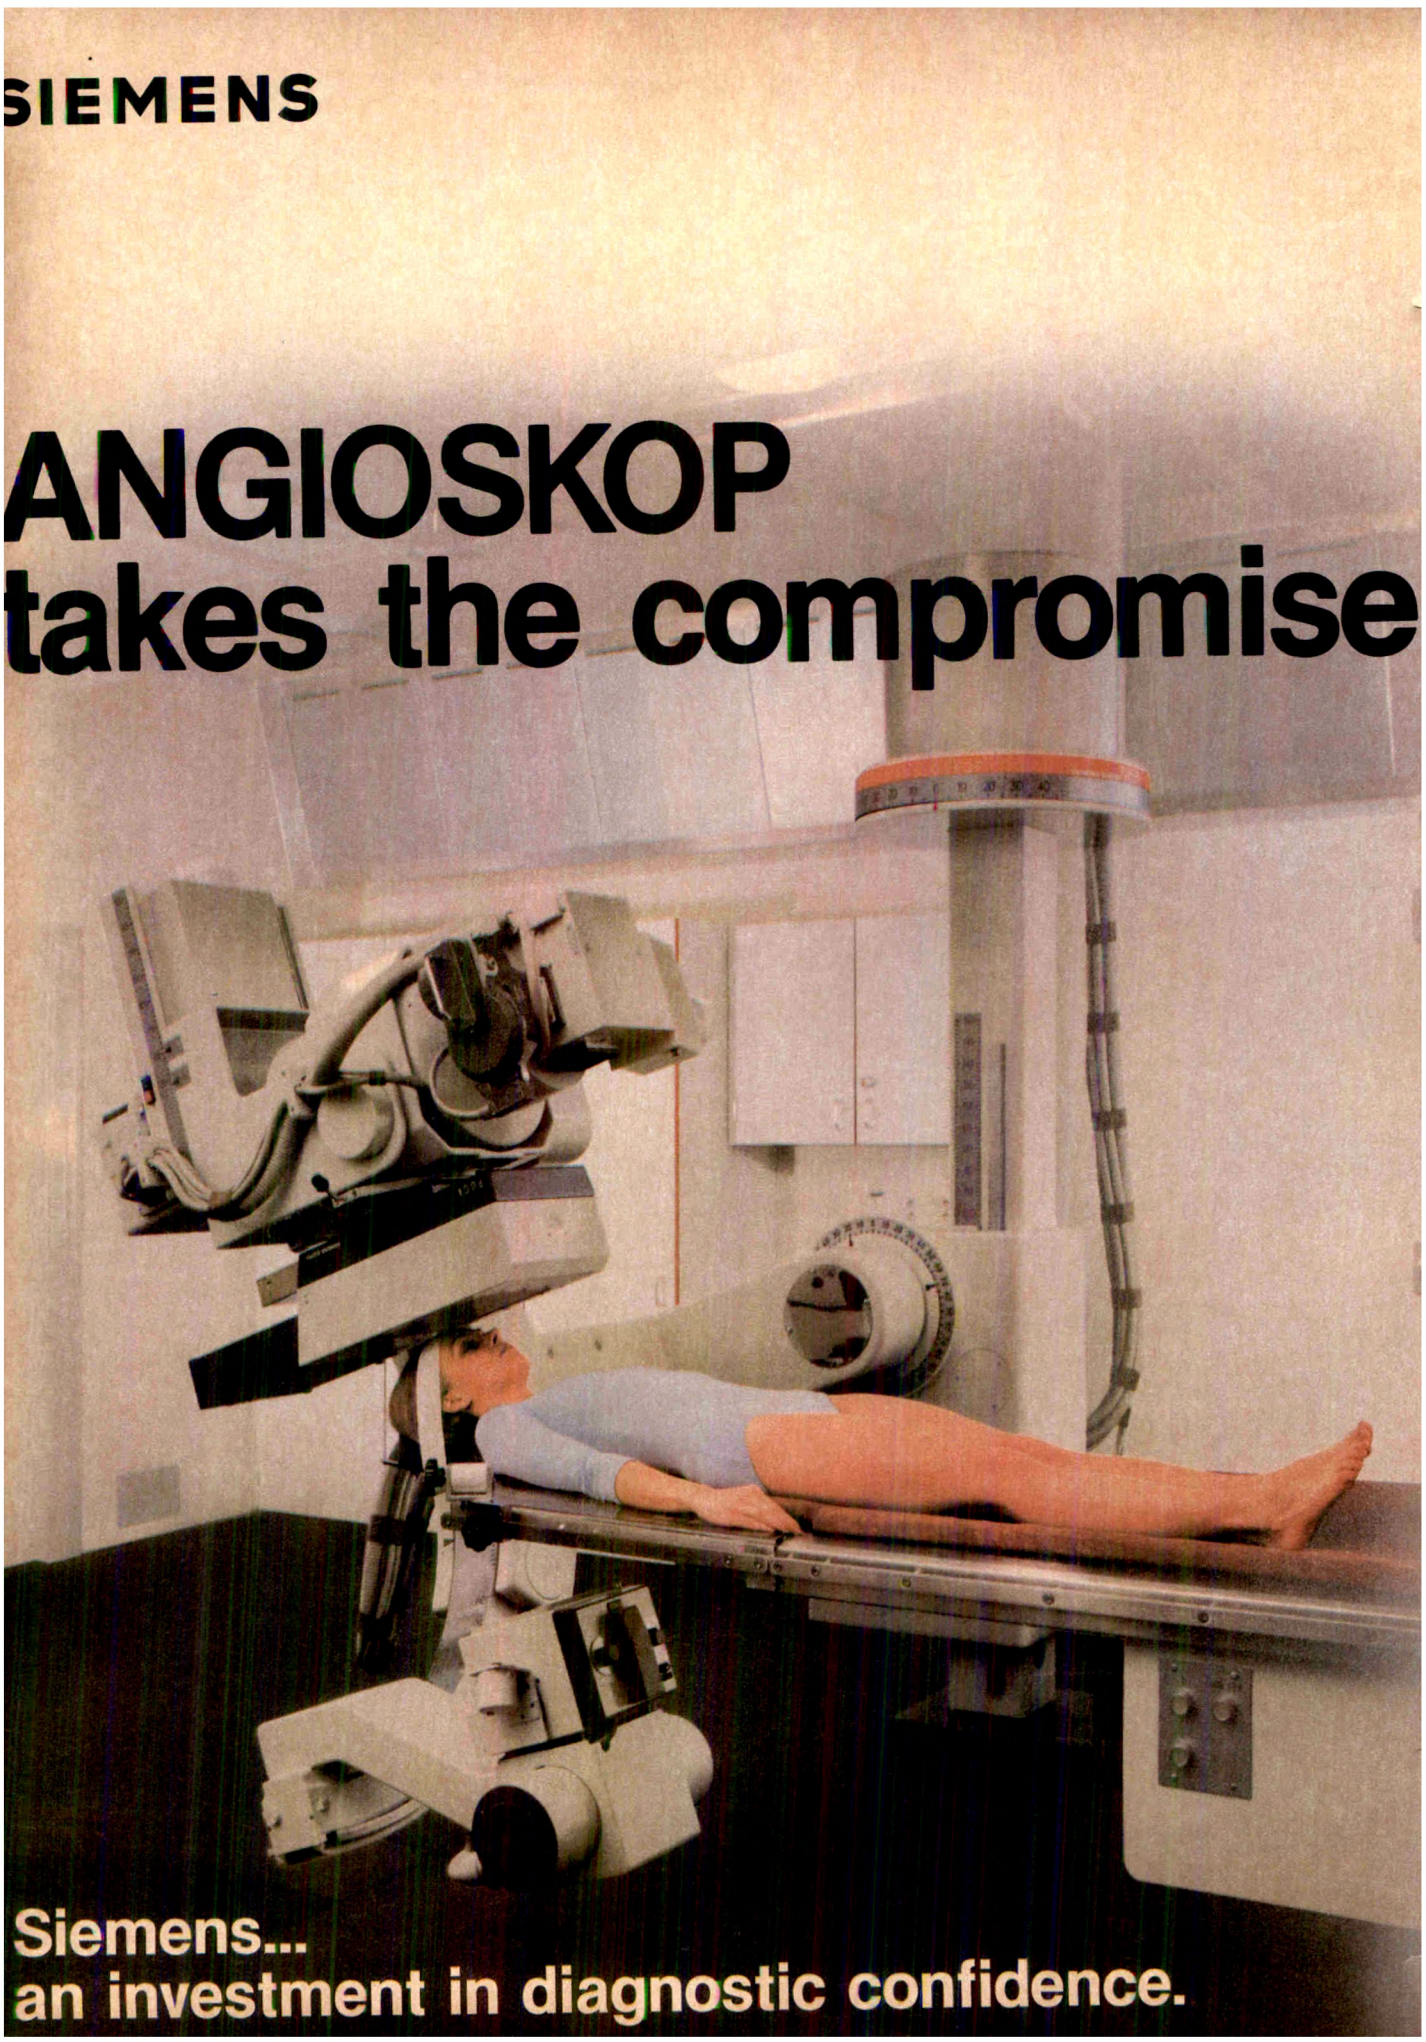
SIEMENS

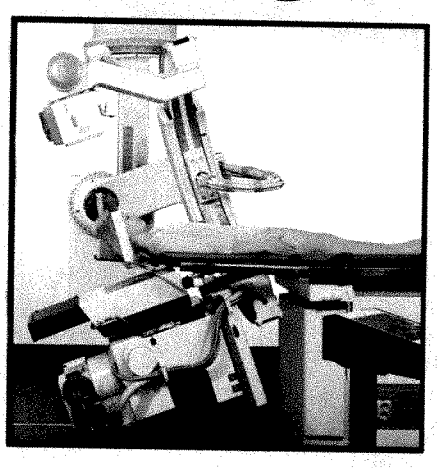
ANGIOSKOP takes the compromise

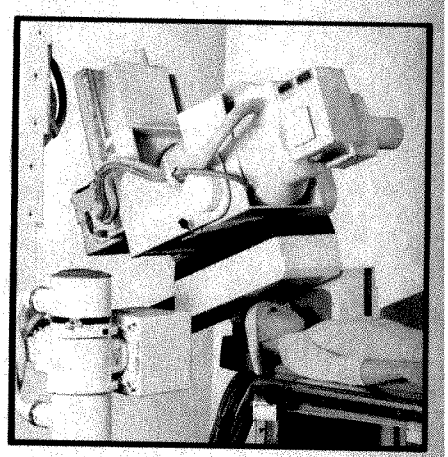


Siemens...
an investment in diagnostic confidence.

out of angiography.

When you invest in angiography equipment, there's no need for compromise. You can select an imaging system designed to optimize operator efficiency and clinical versatility. The ANGIOSKOP overcomes the typical limitations of other systems. That's why it's the "no-compromise" system. See for yourself. Compare the facts and discover the ANGIOSKOP advantage.





A.P./P.A. Studies
The typical compromise: True a.p. projection is not possible.
The ANGIOSKOP advantage: A C-arm system that easily positions to a.p. for classic peripheral studies including leg arteriography.

Oblique Studies
The typical compromise: Restricted patient access.
The ANGIOSKOP advantage: An imaging system that doesn't get in the way between clinician and patient. Our C-arm design eliminates the usual hinderances and provides easy access.

Contact Studies
The typical compromise: Inadequate working height.
The ANGIOSKOP advantage: Vertical adjustment of the isocenter to maintain an efficient and comfortable working height at all times.

Cine Studies
The typical compromise: Limited imaging applications.
The ANGIOSKOP advantage: A universal system that is well suited for cine technique and adaptable to perform all imaging modalities.

Focal Spot Selection
The typical compromise: Double focus tubes.
The ANGIOSKOP advantage: A unique triple focus tube for full range performance, minimizing geometric or motion unsharpness.

X-Ray Generator System
The typical compromise: Complex technique selection.
The ANGIOSKOP advantage: A new special procedure D.C. generator—the PANDOROS 1200A. Features convenient anatomic program selection from a single control desk for all modalities.

...And Digital Subtraction Angiography
The ANGIOSKOP allows all projection capabilities essential for optimum digital subtraction angiography. And Siemens offers a choice of digital imaging systems to match your clinical requirement.

To learn more about how the ANGIOSKOP can help uncomplicate your angiographic procedures, contact your local representative or

Ischemic
heart disease...
malignant
ventricular
arrhythmias...

ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

To reduce the risk of potentially fatal arrhythmias in such patients

QUINAGLUTE® 324 mg DURA-TABS®

(quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

QUINAGLUTE® (quinidine gluconate) DURA-TABS®

INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:

1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock). **2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.

Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.

ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea. Less frequently encountered adverse reactions:

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

"Thank you" to the physicians of America

A sharp drop in prescriptions for TYLENOL® with Codeine followed the recent Extra-Strength TYLENOL® Capsules incident. Patients expressed concern to their physicians even though TYLENOL with Codeine is a prescription product.

We are sincerely grateful to the physicians of this country for taking the time to reassure their patients and allay their anxieties about TYLENOL with Codeine.

The degree of reassurance needed by so many patients—and still needed by some—has re-emphasized the physician's role in the health care system.

We appreciate your continued support in returning TYLENOL with Codeine to its position of trust, dependability, and confidence.

brief summary of prescribing information.

TYLENOL® with Codeine ©

(acetaminophen with codeine)

TABLETS and CAPSULES:
acetaminophen 300 mg plus codeine phosphate:
No. 3—30 mg (½ gr); No. 4—60 mg (1 gr)

Summary of Prescribing Information

Description

Tablets: Contain codeine phosphate*: No. 1—7.5 mg (⅛ gr); No. 2—15 mg (¼ gr); No. 3—30 mg (½ gr); No. 4—60 mg (1 gr)—plus acetaminophen 300 mg.

Capsules: Contain codeine phosphate*: No. 3—30 mg (½ gr); No. 4—60 mg (1 gr)—plus acetaminophen 300 mg.

Elixir: Each 5 ml contains 12 mg codeine phosphate* plus 120 mg acetaminophen (alcohol 7%).

***Warning:** May be habit forming.

Actions: Acetaminophen is an analgesic and antipyretic; codeine an analgesic and antitussive.

Contraindications: Hypersensitivity to acetaminophen or codeine.

Warnings: *Drug dependence:* Codeine can produce drug dependence of the morphine type and may be abused. Dependence and tolerance may develop upon repeated administration; prescribe and administer with same caution appropriate to other oral narcotics. Subject to the Federal Controlled Substances Act.

Usage in ambulatory patients: Caution patients that codeine may impair mental and/or physical abilities required for performance of potentially hazardous tasks such as driving a car or operating machinery.

Interaction with other CNS depressants: Patients receiving other narcotic analgesics, general anesthetics, phenothiazines, other tranquilizers, sedative-hypnotics or other CNS depressants (including alcohol) with this drug may exhibit additive CNS depression. When such a combination is contemplated, reduce the dose of one or both agents.

Usage in pregnancy: Safe use not established. Should not be used in pregnant women unless potential benefits outweigh possible hazards.

Pediatric use: Safe dosage of this combination has not been established in children below the age of three.

Precautions: *Head injury and increased intracranial pressure:* Respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a pre-existing increase in intracranial pressure. Narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.

Acute abdominal conditions: Codeine or other narcotics may obscure the diagnosis or clinical course of acute abdominal conditions.

Special risk patients: Administer with caution to certain patients such as the elderly or debilitated and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, and prostatic hypertrophy or urethral stricture.

Adverse Reactions: Most frequent: lightheadedness, dizziness, sedation, nausea and vomiting, more prominent in ambulatory than in nonambulatory patients; some of these reactions may be alleviated if the patient lies down. Others: euphoria, dysphoria, constipation and pruritus.

Dosage and Administration: Dosage should be adjusted according to the severity of the pain and the response of the patient. It may occasionally be necessary to exceed the usual dosage recommended below in cases of more severe pain or in those patients who have become tolerant to the analgesic effect of narcotics. TYLENOL with Codeine tablets and capsules are given orally. The usual adult dose is: Tablets No. 1, No. 2, and No. 3 and capsules No. 3: One or two every four hours as required. Tablets and capsules No. 4: One every four hours as required. TYLENOL with Codeine elixir is given orally. The usual doses are **Children (3 to 6 years):** 1 teaspoonful (5 ml) 3 or 4 times daily; **(7 to 12 years):** 2 teaspoonsful (10 ml) 3 or 4 times daily; **(under 3 years):** safe dosage has not been established. **Adults:** 1 tablespoonful (15 ml) every 4 hours as needed.

Drug Interactions: CNS depressant effect may be additive with that of other CNS depressants. See Warnings.

For information on symptoms/treatment of overdosage, see full prescribing information.

Full directions for use should be read before administering or prescribing.

TYLENOL with Codeine tablets and capsules are manufactured by McNeil Pharmaceutical Co., Dorado, Puerto Rico 00646.

Caution: Federal law prohibits dispensing without prescription.

Electrophysiologic Testing in the Evaluation of Patients With Syncope of Undetermined Origin

DAVID S. HESS, MD, FRED MORADY, MD, and MELVIN M. SCHEINMAN, MD

Thirty-two patients were prospectively evaluated for syncope (recurrent in 26 patients) with conventional neurologic and cardiovascular testing without elucidation of a cause. All patients underwent invasive electrophysiologic studies to assess sinus nodal function, atrioventricular conduction, and the inducibility of supraventricular and ventricular tachycardia (VT). Eleven patients (34%) were found to have laboratory-induced VT, 5 patients (15%) had evidence of sinus nodal dysfunction, 1 patient (3%) had infra-His atrioventricular block during atrial pacing, and 1 patient (3%) had probable quinidine-related VT. The remaining 14 patients had no detectable abnormalities during electrophysiologic study. After a mean follow-up period of 21.3 ± 1.2 months, 10 of the 11 patients with inducible VT were asymptomatic while receiving laboratory-directed antiarrhythmic therapy, and 1 patient died from ventricular fibrillation after discontinuing the chosen antiarrhythmic regimen. Five of the remaining 7 patients with an electrophysiologic abnormality were asymptomatic after implantation of a permanent pacemaker or alteration of previous drug therapy, or both. The 14 patients with a normal electrophysiologic study were treated empirically, with recurrent syncope occurring in 4 of these patients during the follow-up period. Invasive electrophysiologic studies provided a presumptive diagnosis in 56% of patients with syncope of undetermined origin. Previously unsuspected VT accounted for 61% (11 of 18) of the detected abnormalities. Therapy specific for the electrophysiologic abnormality was usually successful in preventing recurrent syncope.

Since Scherlag et al[1] first recorded the His bundle potential in man in 1969, invasive electrophysiologic techniques have been employed in a variety of clinical settings to evaluate cardiac impulse formation and conduction. Although these invasive methods were initially limited to the assessment of sinus nodal function and atrioventricular conduction,[2,3] recent studies have demonstrated that spontaneously occurring supraventricular and ventricular arrhythmias can be reliably reproduced in the electrophysiology laboratory.[4–9] This ability to provoke clinical tachyarrhythmias has also provided the foundation for the laboratory assessment of antiarrhythmic therapy.[10–15]

Several published studies have evaluated sinus node function and atrioventricular conduction in patients with syncope.[16,17] These studies were primarily designed to detect occult bradyarrhythmias and were not employed to provoke tachyarrhythmias. The present study was undertaken to assess the value of comprehensive invasive electrophysiologic techniques in patients with syncope but no discernible cause after thorough medical and neurologic evaluation. The study was designed to detect both bradyarrhythmias and previously unsuspected supraventricular and ventricular tachyarrhythmias with invasive electrophysiologic methods.

From the Department of Medicine, Division of Cardiology, University of California, San Francisco, California. Manuscript received March 2, 1982; revised manuscript received June 7, 1982, accepted June 16, 1982.

Address for reprints: David S. Hess, MD, Division of Cardiovascular Medicine and Surgery, Memorial Medical Center, 3625 University Boulevard South, Jacksonville, Florida 32216.

Methods

Clinical evaluation and characteristics: Thirty-two patients with syncope referred to the Cardiology Service of the University of California Medical Center from January 1, 1979 to October 1, 1980 were evaluated with conventional medical and neurologic techniques. Syncope was defined as a clinical syndrome characterized by abrupt, transient loss of consciousness with inability to maintain postural tone. All patients underwent a complete medical history, physical examination, and routine laboratory testing. Postural vital signs were recorded in all patients, and individual right and left carotid sinus massage was performed during continuous electrocardiographic (ECG) monitoring. The history was reviewed with special emphasis on the situation and environment at the time of syncope, and, when possible, witnesses to the episode were interviewed. Neurologic consultation was

obtained in all patients. Eighteen patients had both brain imaging (15 by computerized tomography, 1 by radionuclide technique, and 2 by angiography) and electroencephalography. Five patients had only electroencephalograms and 2 had only computerized tomography. At the recommendation of the consulting neurologist, 7 patients had neither procedure performed. Patients had an average of 49.5 ± 5.7 hours of coronary care unit monitoring and 52.0 ± 4.0 hours of ambulatory ECG monitoring. Exercise treadmill testing was carried out if the syncope was related to exertion or associated with chest pain. Left ventricular function was assessed with either M-mode and 2-dimensional echocardiography, gated radionuclide wall motion study, or cardiac catheterization.

There was no evidence of seizure disorder, supraventricular or ventricular tachycardia, bradyarrhythmia (heart rate <45 beats/min), postural hypotension, carotid sinus hypersensitivity, or fixed obstructive valvular heart disease in any patient. During the periods of continuous ECG monitoring, no patient had >30 premature ventricular depolarizations/hour or runs of ≥3 consecutive premature ventricular depolarizations.

The clinical characteristics of the 32 patients (22 men and 10 women) are outlined in Table I. The patients ranged in age from 28 to 87 years (mean 60.2 ± 3.4) and had had 1 to 10 syncopal episodes (mean 3.8 ± 0.5) over an average period of 19.6 ± 5.0 months. Six patients had had only 1 syncopal episode but in 5 of these cases significant morbidity had been associated with the syncope (automobile accident in 2 patients, fractured hip in 1 patient, cerebral concussion in 1 patient, and basilar skull fracture in 1 patient). These patients were entered into the study on a compassionate basis when the conventional evaluation failed to determine a cause.

Five patients had a history of mild to moderate hypertension (1 with congestive heart failure), 7 patients had atherosclerotic coronary artery disease (1 with congestive heart failure), and there was 1 patient each with mitral valve prolapse, systemic sarcoidosis, hypertrophic obstructive cardiomyopathy, rheumatic mitral regurgitation, and congestive cardiomyopathy. Fifteen patients had no underlying organic heart disease.

The initial electrocardiogram demonstrated left bundle branch block in 3 patients, right bundle branch block with left anterior hemiblock in 3 patients, and right bundle branch block with left posterior hemiblock in 1 patient. Six patients had left ventricular hypertrophy and 3 patients had evidence of old myocardial infarction. Six patients had been taking digoxin, 6 patients quinidine, and 3 patients propranolol at the time of the last recorded syncopal episode.

* Unsustained ventricular tachycardia lasting 8 to 21 beats. † Postpacing pauses in the third through ninth complexes after overdrive pacing at a cycle length of 400 ms. ‡ Frequent protein meals to prevent hypoglycemia.

Electrophysiologic testing: After obtaining informed consent, patients were studied in the fasting state without premedication. Except for 1 instance, antiarrhythmic drugs and digoxin had been discontinued for 5 drug half-lives before electrophysiologic study (1 patient was studied while taking quinidine). Two 6 French quadripolar electrode catheters were inserted with use of the Seldinger technique into the femoral vein and positioned against the high right atrium and across the tricupsid valve to record the His bundle potential. A 5 French, 10 cm arterial line was placed percutaneously into the femoral artery to monitor arterial pressure. Scalar ECG leads V_1, I, and III, intracardiac recordings from the high right atrium and His bundle region, along with arterial pressure were simultaneously displayed on an Electronics for Medicine DR 12 ocsilloscope and recorded simultaneously at a paper speed of 100 to 200 mm/s. Pacing was accomplished by means of a programmable stimulator (Bloom, Narberth, Pennsylvania) with a pulse duration of 2 ms at 2 to 3 times diastolic threshold.

Baseline atrioventricular nodal and infranodal (HQ) conduction times were recorded and sinus node function was assessed.[2] The sinus nodal recovery time was determined at paced cycle lengths from 700 to 350 ms, at 50 ms decrements. The subsequent 9 postpacing intervals were analyzed for the presence of secondary pauses.[18] Sinoatrial conduction time was determined by both the extrastimulus and overdrive technique.[19,20]

Atrioventricular nodal and infranodal conduction were assessed during right atrial overdrive pacing at cycle lengths from 700 to 300 ms. Atrioventricular nodal refractoriness was determined during atrial overdrive pacing at a paced cycle length of 500 ms by scanning diastole with single atrial extrastimuli at 10 ms decrements.

Attempts to induce supraventricular tachycardia were carried out by sequentially scanning diastole with 1 or 2 atrial extrastimuli during normal sinus rhythm and during atrial pacing at a cycle length of 500 ms.

The high right atrial catheter was then positioned in the right ventricular apex. Attempts to provoke VT were accomplished by scanning diastole with 1, 2, or 3 ventricular extrastimuli during ventricular overdrive pacing at a cycle length of 500 ms. If the introduction of extrastimuli failed to induce VT, patients underwent burst ventricular pacing (10 to 15 beats) at cycle lengths varying from 500 to 250 ms. As of June 1980, the ventricular stimulation protocol was altered to include left ventricular stimulation in patients who had no inducible or unsustained VT during right ventricular stimulation. Also, if patients had no inducible VT during both right and left ventricular stimulation, the protocol was repeated during an isoproterenol infusion that increased the intrinsic heart rate to 115 to 125 beats/min.

Of the 15 patients considered for left ventricular stimulation, 2 patients did not consent, and 3 patients had atherosclerotic femoral arterial changes which prevented passage of the electrode catheter. In 8 patients with no inducible VT during right ventricular stimulation and in 2 patients with unsustained VT during right ventricular stimulation, left ventricular stimulation was performed. This was accomplished by inserting a 6 French bipolar Goetz catheter into a femoral artery through a sheath and positioning the catheter against the left ventricular apex. The left ventricular stimulation protocol was the same as that outlined for the right ventricle. All patients were given intravenous heparin (3,500 units) during the left ventricular stimulation studies.

Eight patients had no inducible VT with both right and left ventricular stimulation and were considered candidates for repeat stimulation with isoproterenol. Because of coronary artery disease (2 patients), hypertension (1 patient), and failure to consent (1 patient), only 4 patients underwent ventricular stimulation during an isoproterenol infusion. Sustained VT was defined as tachycardia lasting more than 30 seconds or requiring termination by overdrive pacing or electrical cardioversion because of hemodynamic compromise. Unsustained VT was defined as 6 or more consecutive provoked ventricular depolarizations.

At the conclusion of the study, patients with inducible VT underwent serial laboratory electrophysiologic studies to determine an effective antiarrhythmic regimen.[14,15] In patients with abnormalities of sinoatrial conduction or secondary pauses, the decision to permanently pace the patient was left to the judgment of the referring physician. If the infranodal conduction time was markedly prolonged (HQ >70 ms), permanent pacing was recommended, but the final decision was made by the patient's physician. The results of the study in the remainder of the patients were discussed with the referring physician, and subsequent therapy was based on either the study results or the physician's desires. Patients were followed at 3-month intervals, either by 1 of the authors or the referring physician, for a minimum of 16 months.

For the purpose of this study, any patient with the lone abnormal electrophysiologic finding of a prolonged HQ interval (HQ >55 ms) was considered to have a nondiagnostic study. Statistical analysis for association of clinical variables and electrophysiologic findings was performed using McNemar's test for correlated proportions.

Results

Inducible VT: The electrophysiologic diagnosis, treatment, and follow-up information for the 32 patients is outlined in Table I. The most significant finding of the study was the inducibility of VT in 11 patients. Ten patients had VT provoked with right ventricular extrastimuli (8 patients required 3 extrastimuli and 2 required 2 extrastimuli) and 1 patient had VT induced during right ventricular overdrive pacing at a cycle length of 310 ms. Stimulation of the left ventricle and stimulation during an isoproterenol infusion did not result in VT in any patient. VT was sustained in 7 pa-

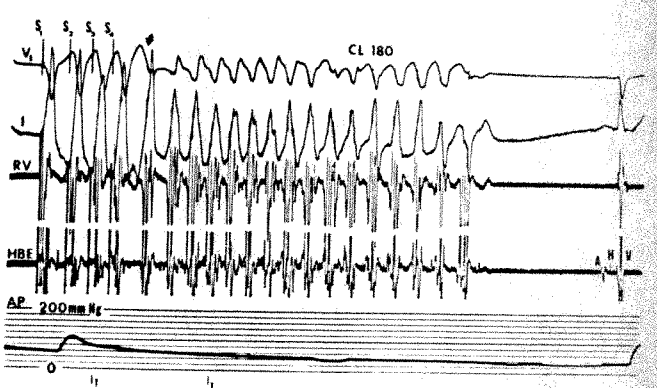

FIGURE 1. Induction of unsustained VT in patient 11 in the baseline state. **Tracings from top to bottom** represent recordings from surface ECG leads V_1 and I, the right ventricular apex (RV), and the His bundle electrogram (HBE). Arterial pressure is displayed on a horizontal grid scale of 0 to 200 mm Hg. The introduction of 3 ventricular extrastimuli produces a 16-beat episode (beginning at the **black arrow**) of VT at a cycle length (CL) of 180 ms. The episode persists for 3 seconds and is accompanied by a fall in arterial pressure from 110 systolic to 30 mm Hg. The episode of VT spontaneously converts to sinus rhythm.

tients and unsustained in 4 patients (Fig. 1). The episodes of sustained VT had an average cycle length of 224 ± 23 ms and required electrical cardioversion in 5 of 7 patients. Patients with unsustained VT had a tachycardia cycle length of 240 ± 38 ms and the episodes averaged 16.3 ± 3.0 beats. In all patients with unsustained VT there was a rapid fall in arterial pressure coincident with the arrhythmia (Fig. 1).

The average age of patients with inducible VT was 63.8 ± 5.4 years. All but 2 of the patients had evidence of organic heart disease by the initial screening tests. Because of the study design, none of the patients with inducible VT had previous evidence of VT during the continuous ECG monitoring. All of these patients had <10 premature ventricular depolarizations per hour during the monitoring period, and only 2 patients had ventricular couplets.

Five of the 11 patients with VT had been taking antiarrhythmic agents during at least 1 of the recorded syncopal spells; 3 patients were receiving no medications, and 3 were taking digoxin and furosemide. The left ventricular ejection fraction was normal (>50%) in 8 patients, and ranged from 35 to 45% in the remaining 3 patients.

The 11 patients with inducible VT underwent a total of 19 stimulation studies to design an effective antiarrhythmic regimen. Eight of 11 patients were placed on a regimen that completely suppressed inducible VT. Two patients had inducible VT despite treatment with conventional medications and were placed on chronic oral amiodarone therapy. One patient was incompletely protected from inducible VT with procainamide therapy, but refused to undergo further pharmacologic testing. In this patient the initial VT cycle length was 350 ms and the duration was 20 beats. After procainamide therapy the tachycardia cycle length increased to 450 ms and the duration was only 6 beats. Treatment with procainamide in this patient produced a junctional rhythm at 35 beats/min, and the patient received a prophylactic permanent pacemaker. Three additional patients with inducible VT also had permanent pacemakers implanted. One patient had an increase of the HQ interval from 85 to 110 ms after treatment with procainamide and amiodarone. Two other patients with bundle branch block and inducible VT (HQ intervals of 80 and 70 ms) received permanent pacemakers at the request of the referring physician.

The treatment and follow-up information for patients with abnormal electrophysiologic studies is illustrated in Figure 2. Patients were followed after the electrophysiologic study for 21.3 ± 1.2 months (range 16 to 36). Ten of the 11 patients with inducible VT are asymptomatic and have not had recurrent syncope during the follow-up period. One patient with inducible VT and a permanent pacemaker for right bundle branch block with left anterior hemiblock died. This patient discontinued the prescribed procainamide therapy 6 months after its initiation, and 1 month later presented with ventricular fibrillation.

One patient received quinidine therapy for atrial fibrillation during the reported syncopal episode. The patient underwent complete invasive testing while taking quinidine and again after the quinidine was discontinued. With the quinidine the patient had reproducible unsustained VT during right ventricular stimulation. The provoked VT had a cycle length of 240 ms and was 11 seconds in duration. A repeat study after quinidine was discontinued revealed no inducible VT during either right or left ventricular stimulation. At the request of the referring physician, the patient received a permanent pacemaker because of left bundle branch block (HQ interval 70 ms). This patient died during the fifth month of follow-up from an acute myocardial infarction.

Patients with clinical evidence of heart disease and those with a prolonged HQ interval had a significantly higher incidence of inducible VT ($p < 0.05$; Table II). In addition, inducible VT was more common in older patients (>50 years old) and in patients with abnormal electrocardiograms. Because of the small number of patients in each subgroup, these latter 2 associations did not reach statistical significance (Table II).

An analysis of the Holter monitor recordings of patients with and without inducible VT failed to reveal any significant difference in the frequency, prematurity, or repetitive nature of the premature ventricular depolarizations. The exclusion from the protocol of patients with frequent premature ventricular depolarizations was probably responsible for the latter observation.

Sinus node dysfunction and atrioventricular block: Five patients had evidence of sinus nodal dysfunction during invasive testing, which was not apparent during the monitoring period. None of these patients had an abnormality in sinus node recovery time, but 1 had abnormal secondary pauses. Two patients had sinoatrial entrance block, and 2 had abnormal sinoatrial conduction times demonstrated by the extrastimulus technique. Three of these patients had no underlying heart disease, 1 had coronary artery disease, and 1 had mild hypertension (taking no medications).

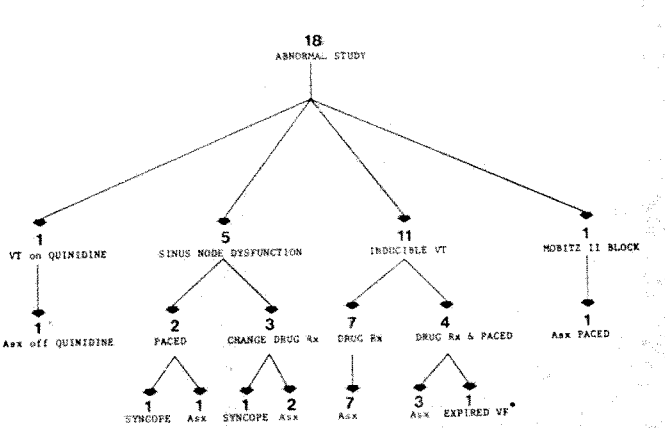

FIGURE 2. Schematic representation of the diagnosis, treatment, and follow-up in 18 patients with an abnormal electrophysiologic finding. Abbreviations are the same as in Table I, with the addition that Asx denotes asymptomatic. The **asterisk** indicates a patient who died after having discontinued the prescribed procainamide therapy.

Therapy varied in this subgroup of patients. Two patients received permanent pacemakers, 1 patient's previous propranolol therapy was discontinued and 2 patients were observed with no treatment. During the follow-up period (Fig. 2), 1 patient with a normally functioning pacemaker had recurrent syncope (at 9 months of follow-up) and 1 patient who was observed without specific treatment had recurrent syncope (at 2 months of follow-up). The remaining 3 patients were asymptomatic.

One patient with coronary artery disease and right bundle branch block with left anterior hemiblock (HQ interval of 60 ms) had infra-His block induced during right atrial overdrive pacing. During atrial overdrive pacing at a cycle length of 480 ms, periods of 1 to 1 atrioventricular conduction were spontaneously interrupted by periods of 2 to 1 infra-His block. The patient was asymptomatic 36 months after pacemaker implanation.

Patients with normal and nondiagnostic electrophysiologic studies: The remaining 14 patients had either normal (12 patients) or nondiagnostic (2 patients) electrophysiologic studies, and were treated empirically. The treatment and follow-up of these patients are summarized in Figure 3. Four of these patients received permanent pacemakers. A patient with systemic sarcoidosis and left bundle branch block (HQ interval 75 ms) was asymptomatic 20 months after pacemaker implantation. Three patients with recurrent syncope, but normal electrophysiologic studies (HQ interval 35 to 40 ms) underwent pacemaker insertion at the request of the referring physician. Two of these patients had recurrent syncope during the follow-up (6 and 12 months) and the other is asymptomatic. Three patients were taking quinidine for atrial premature depolarizations at the time of the recorded syncopal episodes, but none had a prolonged QT interval. Electrophysiologic testing was normal in these patients in the absence of quinidine and they have remained asymptomatic since chronic quinidine therapy was discontinued. One patient was found to have hypoglycemia (serum glucose level 35 mg/100 ml) during a subsequent presyncopal episode and is now asymptomatic on a high protein diet. Of the remaining 6 patients with normal electrophysiologic studies, 1 patient was asymptomatic with no treatment, 2 patients were asymptomatic with empiric procainamide therapy, and 1 patient was asymptomatic with aspirin therapy. The remaining 2 patients have had multiple recurrent syncopal episodes despite empiric therapy with antiarrhythmics, aspirin, and anticonvulsants.

Discussion

The cause of syncope is often apparent after obtaining a complete medical history and physical examination.[21–23] In patients without an obvious cause of syncope, ambulatory ECG monitoring has provided a probable cause in 48 to 64% of patients.[24,25] Despite this improvement in diagnostic ability, a significant percentage of patients with syncope have no discernible cause.

The present study was designed to evaluate the select subgroup of patients with recurrent syncope in whom there was no obvious cause. Since the patient selection critically affects the study's results and conclusions, we attempted to set stringent inclusion criteria yet still have a representative sample of patients with syncope. Consequently, patients with previously documented causes were excluded from the study. The long period of continuous ECG monitoring was designed to eliminate patients with easily detectable sinus nodal dysfunction, atrioventricular block, and frequent tachyarrhythmias. Patients with underlying bundle branch block, on the other hand, were accepted into the study if there was no evidence of second- or third-degree atrioventricular block during the course of the evaluation. By ensuring that the cause of syncope was "unknown" in our study group, the sensitivity of the electrophysiologic study could be evaluated. In addition, by selecting patients with recurrent syncope (26 of 32 patients), treatment interventions could be accurately evaluated over an appropriate clinical follow-up period.

TABLE II Association of Clinical and Laboratory Variables With Inducible VT

Clinical or Laboratory Variable	Incidence of VT	
Heart disease present	53% (9/17)	
Heart disease absent	13% (2/15)	$p < 0.05$
HQ >55 ms	64% (7/11)	
HQ ≤55 ms	19% (4/21)	$p < 0.05$
Age >50 yr	41% (9/22)	
Age ≤50 yr	20% (2/10)	NS
Abnormal ECG	47% (8/17)	
Normal ECG	20% (3/15)	NS

The ratio within the parentheses represents the number of patients with VT (numerator) and the number of patients with the descriptive parameter (denominator). NS = not significant.

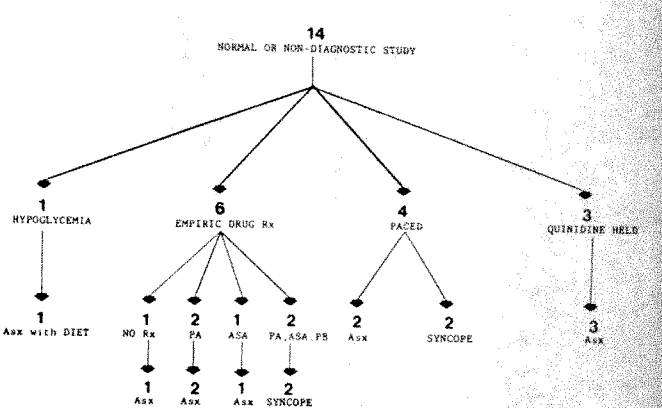

FIGURE 3. Schematic representation of the treatment and follow-up in 14 patients with a normal or nondiagnostic electrophysiologic study. Abbreviations are as in Table I and Figure 2. See text for details.

VT as a cause of syncope: The most significant finding in our study was the demonstration of laboratory-induced VT in 11 of 32 patients. Since 9 of the 11 patients had evidence of organic heart disease, this finding may have been a laboratory phenomenon related to the ventricular stimulation technique and not to the patient's clinical syncope. This explanation seems unlikely for 2 reasons. First, Vandepol et al[26] and Fisher et al[13] recently reported on the specificity of ventricular stimulation studies in control groups of patients with organic heart disease. Of 509 such patients studied, only 5 had inducible VT in the laboratory (2 of these 5 patients had a history of unexplained syncope). Because neither investigator routinely employed 3 extrastimuli in their studies, the reported specificity of 99% may not apply to our stimulation protocol. However, it is unlikely that our protocol produced a false-positive study in 34% of the patients.

The follow-up information provides further support that the laboratory induction of VT was related to our patients' syncope. After laboratory-directed antiarrhythmic therapy was initiated, no patient had a subsequent syncopal episode with the tested regimen. These follow-up data are complicated by the fact that 4 of these patients also received permanent pacemakers. Thus, relief of symptoms in these 4 patients cannot be solely credited to the prevention of occult VT. However, 1 of these 4 patients did have recurrent syncope and ventricular fibrillation after discontinuing the prescribed procainamide. The remaining 7 patients with inducible VT were treated with only the laboratory-directed antiarrhythmic regimen; all 7 have remained asymptomatic. Since syncope had been recurrent in 6 of these 7 patients, the absence of symptoms in the follow-up period is indirect evidence that VT was the cause of syncope. An additional observation is that 5 of these 7 patients had previously been treated with empiric antiarrhythmic therapy, but despite therapy had recurrent syncope. Only when these 5 patients were treated with a drug regimen that suppressed the laboratory induction of VT did their syncope abate. Thus, laboratory induction of VT not only provided a diagnosis in these patients, but also a rational basis for effective therapy.

The observation of unsustained VT in the laboratory is consistent with the clinical setting of brief episodes of loss of consciousness. However, in the 7 patients with sustained VT, either rapid overdrive pacing (2 patients) or electrical cardioversion (5 patients) was required to terminate the patient's laboratory arrhythmia. What would have occurred in these patients with further observation is only conjecture, but perhaps neural, metabolic, or cardiac factors would have resulted in spontaneous conversion to sinus rhythm. In subsequent patients (not included in this study), we have occasionally observed spontaneous conversion of laboratory-induced VT to sinus rhythm after 30 to 40 seconds without external intervention. We hypothesize that spontaneous conversion probably occurred in the study patients during their clinical episodes of syncope. An alternative explanation is that the clinical VT is unsustained (possibly an effect of antiarrhythmic drugs in some patients), but the laboratory VT is sustained in the baseline state.

In our study group, VT was more commonly found in older patients, in patients with an abnormal baseline electrocardiogram, and in patients with an abnormal HQ interval. These factors are probably not independent predictors of VT, but rather reflect the presence of the underlying organic heart disease. In addition, our laboratory protocol included the introduction of up to 3 ventricular extrastimuli at multiple coupling intervals in order to facilitate the induction of VT. A less aggressive ventricular pacing protocol, particularly in a group of young patients with syncope and without organic heart disease, would probably yield a lower incidence of VT.

Sinus node dysfunction and bundle branch block: Because the study design excluded patients with extreme bradycardia and obvious sinus node dysfunction, the abnormalities discovered with sinus node testing were subtle. Although several studies suggest that implantation of permanent pacemakers will relieve symptoms of dizziness and syncope in patients with abnormal sinus node function, others have demonstrated no improvement in symptoms.[27] Since detected abnormalities in sinus node function and symptoms are not always related, pacemaker implantation was not performed in all our patients. From the follow-up information in our small group of patients, it is not clear whether the observed electrophysiologic abnormalities were related to the clinical symptoms.

Of the 7 patients presenting with syncope and bundle branch block, only 1 had infra-His block during right atrial overdrive pacing. Dhingra et al[28] reported this finding in 15 of 496 patients with bundle branch block undergoing electrophysiologic study. During a 3.4 year follow-up, 7 of these 15 patients progressed to symptomatic complete atrioventricular block. Thus, intermittent complete atrioventricular block was the probable cause of syncope in our patient. Our remaining 6 patients with bundle branch block also underwent permanent pacemaker implantation. Since 5 of these 6 patients had other demonstrable causes of syncope, the efficacy of pacemaker insertion cannot be adequately evaluated. Identification of a possible cause of syncope other than progression to complete atrioventricular block is consistent with reports in the literature. In studies by Scheinman et al[16] and Dhingra et al[29] only a small percentage of patients with bundle branch block and syncope had documented progression to high-degree atrioventricular block. The cause was either unknown or secondary to other disorders in the remainder of their patients. While there appears to be a general consensus that patients with bundle branch block and recurrent syncope should be treated with a permanent ventricular pacemaker, our observation would support the need for detailed electrophysiologic studies in these patients. As a result of such studies, the physician should decide whether optimal therapy includes a permanent pacemaker with or without antiarrhythmic drugs.

Other investigators have employed similar techniques in evaluating patients with syncope.[30,31] In a study of

25 patients with recurrent syncope, DiMarco et al[30] reported a presumptive diagnosis in 17 patients. Because these investigators included a prolonged atrioventricular nodal refactory period and a prolonged HQ interval as causes of syncope, the reported sensitivity of their protocol (68%) exceeds that of the present study (56%). Since it remains controversial whether these laboratory abnormalities are related to clinical symptoms, similar abnormalities were not considered of diagnostic value in our study. A second difference between the 2 studies relates to the patient follow-up. In these types of studies, evidence supportive of a presumptive diagnosis is obtained by monitoring patients for the recurrence of symptoms during treatment. In DiMarco's study, patients with inducible VT were followed for abbreviated periods, with 5 of 9 such patients being followed for only 6 months or less. In contrast, patients with inducible VT in the present study were followed for a minimum of 16 months, with an average follow-up of 20.1 ± 1.8 months. The absence of syncope during our treatment period provides stronger indirect evidence that this laboratory-induced arrhythmia was the cause of the clinical symptoms.

In our series, complete electrophysiologic studies resulted in definitive findings in 18 of 32 patients. Two of these patients died during the follow-up, and 14 of the remaining 16 are asymptomatic on laboratory-directed therapy. The most commonly detected abnormality was occult VT, and the response of patients with this finding to laboratory-directed antiarrhythmic therapy was excellent. Our observations demonstrate the value of invasive electrophysiologic studies in determining the cause and guiding therapy in patients with syncope of undetermined origin. These studies may allow for rapid diagnosis and institution of appropriate therapy and thus avoid the costs of repeated hospitalization or Holter examinations as well as the morbidity resulting from recurrent syncope. We believe provocative electrophysiologic studies are useful in selected patients with recurrent syncope in whom the conventional evaluation has been unrevealing.

Value of the H-Q Interval in Patients With Bundle Branch Block and the Role of Prophylactic Permanent Pacing

MELVIN M. SCHEINMAN, MD, ROBERT W. PETERS, MD, MARY JANE SAUVÉ, RN, MS, JAWAHAR DESAI, MD, JOSEPH A. ABBOTT, MD, JOHN COGAN, MD, BARRY WOHL, MD, and KATHERINE WILLIAMS, BS

His bundle electrograms were obtained in 313 patients with chronic bundle branch block who were followed for a mean period of almost 3 years. The infranodal conduction time (H-Q interval) was <55 ms in 97 patients (Group I), 55 to 69 ms in 99 patients (Group II), and ≥70 ms in 117 patients (Group III). There was a higher incidence of organic heart disease in patients in Group III, but the groups were otherwise comparable. On follow-up study, mortality and the incidence of sudden death were similar among the groups, but patients in Group III had a greater incidence of progression to high degree atrioventricular block (HDB) than did those in Groups I and II (14 of 117 [12%] versus 4 of 97 [4%] and 2 of 99 [2%], p <0.01, respectively). High degree block was found in 4 of 17 (24%) patients with an H-Q interval (H-Q) ≥100 ms.

Sixty-two patients underwent permanent prophylactic pacemaker insertion at the discretion of the referring physician and were compared with 231 patients who did not. Paced patients had a higher incidence of transient neurologic symptoms and prolonged H-Q, but the groups were otherwise comparable. On follow-up study, mortality and the incidence of sudden death were similar among the groups, but symptom relief was significantly more common among patients with pacemakers.

In conclusion, in our population (1) H-Q ≥70 ms was an independent risk factor for progression to HDB, (2) H-Q ≥100 ms identified a subgroup at particularly high risk, and (3) prophylactic pacemakers relieved neurologic symptoms but did not prolong life.

Patients with chronic bundle branch block have an increased risk for the development of complete atrioventricular (AV) block.[1–5] The recent introduction of techniques for ready recording of the His bundle potential in man has been applied to patients with bundle branch block.[6,7] Prolongation of the infranodal conduction time in a patient with bundle branch block signifies associated disease in either the unblocked bundle branch or the His bundle. Theoretically, a prolonged H-Q interval suggests advanced conduction system disease and may conceivably identify a subgroup at high risk for developing AV block or sudden death. The clinical significance of H-Q prolongation remains controversial.[8–10] We previously reported short-term prospective follow-up data in patients with chronic bundle branch block who underwent His bundle recordings.[11] In the present report, this experience is updated with a larger cohort to appraise the clinical significance of a prolonged H-Q interval more accurately. In addition, we are updating our experience with prophylactic permanent pacing in these patients.[12]

Methods

The methodology for this study was described in detail previously.[11] In brief, all patients with the electrocardiographic pattern of chronic bundle branch block were included in the present study. Patients from the cardiology clinics of various San Francisco Bay Area hospitals as well as patients referred for electrophysiologic study were included. Patients with bundle branch block and acute myocardial infarction as well as those with second or third degree AV block were excluded from the study.

A complete history, chest roentgenogram, and physical examination were obtained in all patients. His bundle electrograms were obtained using standard techniques. In brief, a multipolar electrode catheter was inserted into the right femoral vein and positioned across the tricuspid valve. The His bundle electrogram and 3 surface electrocardiographic leads were displayed simultaneously on an oscilloscope and recorded (Electronics for Medicine VR-12 recorder). The AV nodal conduction time was measured from the initial high frequency deflection of the low right atrial electrogram to the first high frequency His bundle deflection (A-H), whereas infranodal conduction time was measured from the initial high frequency deflection recorded from the His bundle to the earliest onset of ventricular activation determined from the surface leads (H-Q). Patients who had second and third degree AV block during the His bundle recording were also excluded from study.

Follow-up study: Patients were followed up every 3 months either in the pacemaker and arrhythmia clinic or by referring physicians. Follow-up information was obtained by a public health nurse from patients who did not keep scheduled appointments. When necessary, home visits were made to obtain additional information including 12-lead electrocardiograms. In the event of progression to a higher degree of AV block, electrocardiographic tracings showing AV block were obtained. The diagnosis of second or third degree infranodal block was made on the basis of typical Mobitz type II AV block or periods of complete AV block with slow idioventricular rhythm associated with a different QRS morphology. Only patients with spontaneous AV block were included for study. Excluded were patients who showed AV block in the course of acute myocardial infarction or those with associated electrolyte disorders. In 6 patients the infranodal site of block was confirmed at the time of repeat electrophysiologic study. Patients requiring pacemaker insertion for sinus node disease or those in whom block developed at the level of the AV node were excluded from the study. In the event of death, hospital or coroner's reports, or both, were reviewed and observers were interviewed to determine if death was sudden.

Definitions: The criteria for diagnosis of bundle branch or fascicular block as well as intraventricular conduction delay have been discussed elsewhere.[13]

Congestive heart failure was diagnosed on the basis of physical findings and chest roentgenograms, and the patients were categorized according to the New York Heart Association functional classification. The diagnosis of valvular heart disease was based on physical examination or the results of cardiac catheterization. The diagnosis of cardiomyopathy was made in those patients with myocardial disease without demonstrable cause. For purposes of this study, patients with a history of smoking in excess of 10 cigarettes a day were classified as cigarette smokers. *Sudden death* was defined as unexpected natural death occurring either instantaneously (during sleep) or within 1 hour of the onset of symptoms. *Cardiovascular deaths* were those due to acute myocardial infarction or congestive heart failure.

Sixty-two patients underwent prophylactic pacemaker insertion. None of these patients showed evidence of second or third degree AV block during repeated continuous electrocardiographic monitoring. Pacemaker insertion was performed at the discretion of the referring physician on the basis of neurologic symptoms (syncope, recurrent dizzy spells, or seizures) or electrophysiologic abnormalities, or both. In some patients without symptoms, the nature of their occupation proved to be an important factor in the decision to insert a permanent pacemaker. These patients were seen regularly either by their private physicians or in an arrhythmia and pacemaker clinic. In addition, follow-up study included periodic telephone transmission of the pacemaker rate and stimulus characteristics.

Statistical methods: All data were stored on punch cards and later retrieved using a program written for the IBM model 360/75 computer. All nominal data were tested with the chi-square test or, when numbers were small, with Fisher's exact probability test.[14]

Results

A total of 367 patients with bundle branch block have been entered into the study since March 1972. Twenty-three patients were lost to follow-up study and 19 were excluded either because pacemakers were inserted for sinus node disease (12 patients) or because AV nodal block was demonstrated at repeat study (7 patients). Similarly, 12 patients in whom second or third degree AV block developed as a result of electrolyte abnormality or acute myocardial infarction were not included in the present analysis. The remaining 313 patients form the basis of this report.

TABLE I Clinical and Electrophysiologic Data in Patients With Chronic Bundle Branch Block

Variable	Group I: H-Q 30–54 ms		Group II: H-Q 55–69 ms		Group III: H-Q >70 ms		p Value
	n	%	n	%	n	%	
Patients (n)	97	...	99	...	117	...	
Age (mean ± SD) (yr)	66 ± 13	...	66.6 ± 14	...	66.5 ± 11	...	NS
Total with organic cardiac disease*	85	88	87	88	104	89	NS
Coronary artery disease	63	65	68	67	78	69	NS
Transient neurologic symptoms	58	60	58	59	68	56	NS
Syncope	38	39	40	40	46	39	NS
Congestive heart failure (class III or IV)	18	18.5	22	22	38	32	<0.05†
Follow-up (mo)	34 ± 24	...	34.5 ± 27	...	28 ± 23	...	NS
Progression to 2° or 3° block	4	4	2	2	14	12	<0.001†
Sudden deaths	12/97	14	12/99	12	19/117	16	NS
Cardiac deaths	14/97	14	15/99	15	28/117	24	NS
All deaths	41	42	50	51	57	49	NS

* Organic cardiac disease included patients with coronary artery, primary myocardial, valvular, hypertensive, and congenital heart disease.
† The incidence of organic cardiac disease, severe congestive heart failure, and progression to second (2°) or third degree (3°) AV block was higher in Group III than in either Group I or II.
NS = not significant; SD = standard deviation.

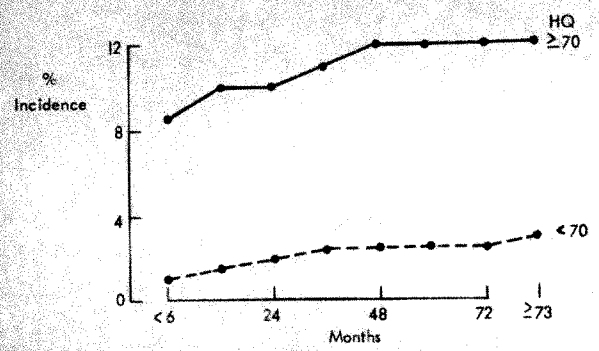

FIGURE 1. Incidence of spontaneous progression to second or third degree infranodal block with in patients an H-Q interval ≥70 ms is compared with that in patients with an H-Q interval <70 ms. The bulk of progression occurs within 6 months of entry into the study.

The patients were divided into 3 groups on the basis of the H-Q interval (Table I). Ninety-seven patients had H-Q intervals of 30 to 54 ms (Group I), 99 had H-Q intervals of 55 to 69 ms (Group II), and 117 had H-Q intervals ≥70 ms (Group III). There was no significant difference in age, incidence of syncope, or transient neurologic symptoms or length of follow-up study among the groups. The majority of subjects had organic heart disease; the most common diagnosis was coronary artery disease (67%).

The incidence of spontaneous progression to second degree or complete AV block was significantly higher in Group III (14 of 117 or 12%) than in Groups I (4 of 97 or 4%) and II (2 of 99 or 2%) ($p < 0.001$). The cumulative incidence of progression to second or third degree AV block for patients with H-Q ≥70 ms and those with H-Q <70 ms is detailed in Figure 1. The bulk of progression occurred in Group III patients within 6 months after entry into the study. Thereafter, a more gradual rate of progression was observed until plateau levels were achieved in both groups after approximately 36 months. The "plateau" may reflect the smaller numbers of subjects still alive at this time.

The risk of progression appears to be quantitatively related to the degree of H-Q lengthening once a critical H-Q interval of 70 ms is exceeded. For example, 17 patients with an H-Q interval of ≥100 ms showed a 23.5% progression rate (4 of 17) over a mean follow-up period of 22 ± 17 months. Most of the patients (13 of 17) had transient neurologic symptoms. Four of 17 had spontaneous progression to second or third degree AV block 11, 12, 18, and 56 months after entry and received pacemakers. Two of the 4 died of severe congestive heart failure. Seven of the 17 patients had prophylactic pacing; of the 7, 6 had transient neurologic symptoms. Five patients died. Three deaths were due to cardiac causes and 2 to noncardiac causes; none died suddenly. Three of 6 patients who did not have pacing died suddenly. Although the group of patients with an H-Q interval of ≥100 ms form a small subgroup within the total study group (17 of 313 [5.1%]), the high spontaneous progression rate is a minimal figure because over half of these patients were treated with prophylactic pacing.

The incidence of sudden death was similar among the groups (Table I). Although total cardiac mortality was higher in patients with marked prolongation of the H-Q interval (Group III) than in the other groups, this difference was not statistically significant. The possibly higher cardiac mortality in Group III may be related to the higher incidence of severe congestive heart failure in this group than in the others (Table I).

The surface electrocardiographic pattern proved to be of limited value in predicting either spontaneous progression to second or third degree AV block or the presence of marked prolongation of the H-Q interval. The various electrocardiographic patterns for each group are summarized in Table II. First degree AV block was significantly more frequent in Group III than in Group I, but this finding proved of limited clinical value. Similarly, there was no significant difference in the incidence of left bundle branch block or a bifascicular block pattern among the 3 groups.

These data identify a subset of patients with bundle branch block at increased risk for the development of AV block and in whom permanent pacemaker insertion might conceivably improve neurologic symptoms and survival. To test this hypothesis, we examined the clinical course of patients in whom permanent pacemakers were inserted prophylactically (in the absence of documented high grade AV block) and unpaced patients. Prophylactic pacemakers were inserted at the discretion of the referring physicians on the basis of

TABLE II Electrocardiographic Patterns in Patients With Chronic Bundle Branch Block

Variable	Group I		Group II		Group III		p Value
	n	%	n	%	n	%	
Patients (n)	97	...	99	...	117	...	...
First degree AV block	26	27	45	45	65	56	<0.001*
Right bundle branch block	22	23	34	34	49	42	<0.02*
Left bundle branch block	29	30	17	17	21	18	NS
Right bundle branch block with left anterior hemiblock	33	34	36	35	29	25	NS
Right bundle branch block with left posterior hemiblock	7	7	5	4	7	6	NS
Intraventricular conduction defect	6	6	7	7	11	9	NS

* There was no significant difference between Groups II and III. However, Group III had a higher incidence of first degree AV block and right bundle branch block than Group I.

TABLE III Comparison of Clinical and Electrophysiologic Findings for Paced and Unpaced Patients

Clinical Variable	Paced Patients: Prophylactically n	%	Paced Patients: For Progression to Second or Third Degree AV Block n	%	Unpaced Patients n	%	p Value
Patients (n)	62	...	20	...	231	...	...

Total deaths	31	50	11	55	108	47	NS

neurologic symptoms or abnormal electrophysiologic findings, or both. No evidence of AV block was found despite repeated 24-hour continuous dynamic electrocardiographic monitoring or observation in a coronary care unit. Clinical and electrophysiologic data for paced and unpaced patients are shown in Table III.

The 62 patients who underwent prophylactic pacemaker insertion were similar with respect to age and cardiac diagnosis compared with the 231 patients who were not paced. Twenty patients who required permanent pacemaker insertion because of progression to second or third degree AV block were analyzed separately. As expected, the incidence of syncope or transient neurologic symptoms as well as an abnormal H-Q interval were greater in the group with prophylactic pacing (Table III). Patients treated with pacemakers had a significantly higher incidence of relief of any neurologic symptoms or syncope than did the unpaced group.

Figure 2 shows follow-up findings in symptomatic prophylactically paced and unpaced patients. Of note was the finding of a high incidence of spontaneous disappearance of symptoms for the unpaced group. In addition, follow-up evaluation revealed the probable causes of symptoms in approximately half of those patients who had persistent transient neurologic symptoms. The causes included episodes of tachyarrhythmia (8 patients), cerebrovascular disease (4 patients), orthostatic hypertension (1 patient), drug use including alcoholism (5 patients), and hypoglycemia (1 patient). Seven of the 8 patients with transient neurologic symptoms who underwent pacemaker insertion because

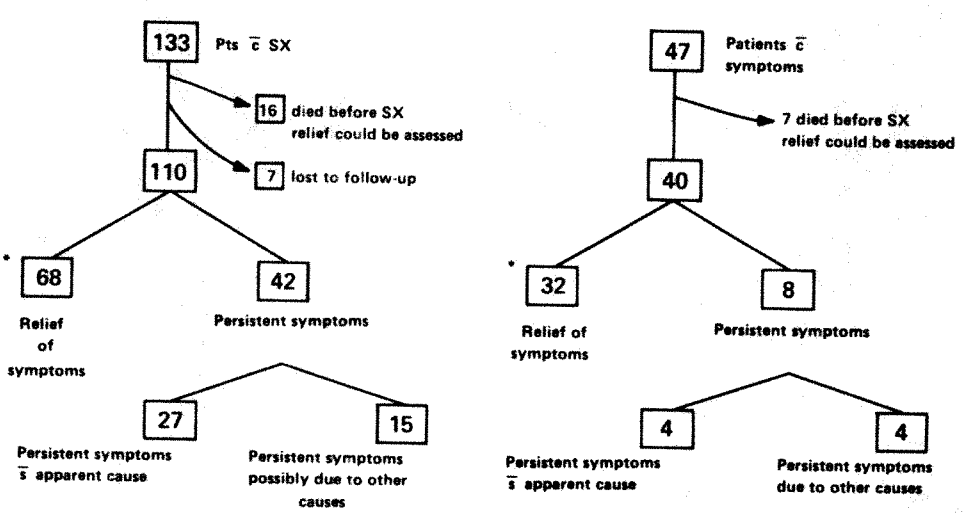

FIGURE 2. Follow-up chart of symptomatic patients who were either not paced (**left**) or paced (**right**). Excluded were 20 patients who underwent pacemaker insertion because of documented spontaneous trifascicular block. The incidence of relief of all transient neurologic symptoms was significantly higher in the paced group. SX = symptoms. **Asterisk** indicates $p < 0.05$.

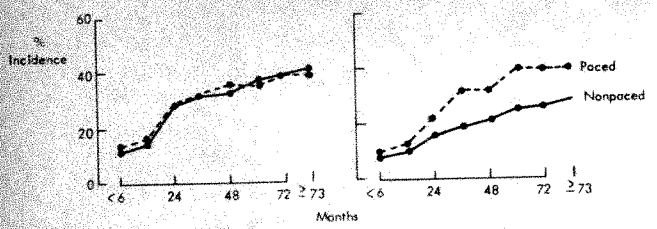

FIGURE 3. Cumulative incidences of cardiac deaths (**left**) and sudden deaths (**right**) for paced and unpaced patients. Although the incidence of sudden death was higher in paced patients at each follow-up interval, the differences were not significant.

of documented AV block had relief of symptoms (not shown in Figure 5).

Similar causes of transient neurologic symptoms were discerned in paced patients who had persistent symptoms after pacemaker insertion. We found no significant difference in the cumulative incidence of either cardiac or sudden deaths between paced and unpaced patients (Fig. 3). Sudden death was greater in the paced groups, but this difference was not significant.

It might reasonably be argued that the incidence of sudden death in the paced group might have been substantially higher had they not undergone prophylactic pacemaker insertion. We therefore compared all nonpaced patients with transient neurologic symptoms and an H-Q interval ≥70 ms with the paced group (Table IV). The 2 groups were comparable with regard to all clinical and electrophysiologic variables. The incidence of relief of syncope (88 versus 55%) and relief of all neurologic symptoms (89 versus 59%) was significantly greater in the paced group, but there was no difference in the incidence of sudden death or cardiac death between these 2 groups. Thus, we found no evidence tht prophylactic pacing increased longevity even when such patients were compared with a group with an expected increased risk for progressive conduction system disease.

Discussion

This report confirms and extends our previous observations relative to the importance of the H-Q interval in patients with bundle branch block. A markedly prolonged H-Q interval represents a clear-cut risk factor for spontaneous progression to second or third degree infranodal block. This increased risk was confined to those patients with an H-Q interval ≥70 ms, who had a 4-fold increase in progression compared with subjects who had either normal or slightly increased H-Q intervals (35 to 69 ms). A new and potentially important finding was the extremely high risk of progression to second or third degree AV block (23.5%) among patients with an H-Q interval ≥100 ms, suggesting a graded increment of risk dependent on the H-Q interval. It is pertinent to compare our data with those of 2 other similarly designed larger prospective studies of patients with bundle branch block.

Our findings confirm the recent report of Dhingra et al[15] involving 517 patients followed for a mean of 3.4 years. They also found an increased risk for spontaneous trifascicular block in patients with prolonged H-Q intervals. The incidence of spontaneous AV block in their study was lower than that in our series (that is, 0.6% for those with a normal H-Q interval versus 4.5% for those with H-V interval prolongation. In addition, our data differ with respect to the cumulative incidence of AV block. In our series, the bulk of spontaneous progression occurred within 6 months of study with a gradual increase to the 36th month of follow-up study followed by a plateau. In contrast, Dhingra et al[15] found a gradual increase in the cumulative incidence of AV block throughout the course of their study. Our results also differ from those of McAnulty et al,[16] who found that the H-Q interval failed to define a high risk subgroup (in terms of progression to complete AV block or sudden death) in 257 patients followed up over an average of 25 months. We believe that differences between studies are best reconciled by the characteristics of the respective

TABLE IV Prophylactically Paced Patients Versus Symptomatic Patients With an H-Q Interval ≥70 ms

patient populations. Patients in the studies by McAnulty et al[16] and Dhingra et al[15] were recruited primarily by mass electrocardiographic screening. In contrast, most of our patients either were referred for study or consented to participate in the study because of symptoms. The ages of their patients as well as the incidence of organic cardiac disease, transient neurologic symptoms, and severe congestive heart failure were less than those in our studies. Earlier reports by Dhingra et al[17] and Denes et al,[18] for example, failed to show an increased risk for progression in those with a prolonged H-Q interval versus subjects with a normal H-Q interval. We hypothesize that as their patients aged, the respective population cohorts developed more similar characteristics which may help to explain the concordance in findings between our most recent studies. It is still a matter of conjecture whether or not the same will prove true for the patients followed up by McAnulty et al.[16] Similarly, the difference in the cumulative incidence of spontaneous AV block in our series compared with that of Dhingra et al[15] probably results from the higher incidence of syncope in our patients. In some of our patients, syncope was probably related to episodic high grade AV block that was eventually diagnosed relatively soon after entry into the study. Of special clinical importance was the finding of a very high incidence of spontaneous progression to complete AV block in patients with atrial pacing-induced AV block.[19]

In the present study, although prophylactic permanent pacing (in a subgroup with either symptoms or a prolonged H-Q interval or both) resulted in a significant decrease in the incidence of syncope, the incidence of sudden death or death was unchanged compared with that in the unpaced group. Similarly, the incidence of sudden death was comparable in the prophylactically paced group and in symptomatic patients with an H-Q interval ≥70 mm who were not treated with pacemakers. We interpret these findings as suggesting that the cause of sudden death was largely related to malignant ventricular arrhythmias, because no evidence of pacemaker malfunction was found in follow-up evaluation. In 2 paced patients undergoing continuous electrocardiographic monitoring, death was documented as due to ventricular fibrillation. These findings are in accord with the observations of Denes et al,[20] who concluded that death in patients with bifascicular block were largely due to ventricular arrhythmias; however, somewhat different results have been reported by other groups.[21,27]

Clinical implications: Conclusions from our data must be interpreted in the light of our study population: almost all had organic cardiac disease and most had transient neurologic symptoms. Therefore, our findings are not comparable to data of epidemiologic surveys of asymptomatic subjects with bundle branch block. In this study group, those with an H-Q interval ≥70 ms had a definite increased risk of progression to spontaneous trifascicular block compared with patients with an H-Q interval <70 ms. The overall risk of progression in patients with an H-Q interval ≥70 ms is still small, and routine prophylactic pacing in asymptomatic patients is not warranted. Transient neurologic symptoms alone may be an unreliable guide in determining the role of prophylactic pacing, because over half the patients with bundle branch block will have spontaneous remission of symptoms and a significant number have symptoms due to cardiac arrhythmias or neurologic, metabolic, or drug-related causes. These findings are in accord with the observations of Dhingra et al,[23] who found a high rate of spontaneous remission of symptoms. In patients with an H-Q interval ≥70 ms with recurrent transient neurologic symptoms (of no known cause), pacing appears to be indicated and will likely result in relief of symptoms, but there is no evidence to suggest that this intervention will prolong life. This conclusion is supported by our follow-up observations in 20 patients who received pacemakers because of documented progression to second or third degree AV block in that cardiac mortality was identical to that in unpaced or prophylactically paced patients; however, a trend toward a lower incidence of sudden death appeared in patients with documented AV block. The ultimate prognosis appears to be related to the severity of the underlying cardiac disease.[12] A new finding in our study is the extremely high incidence of spontaneous progression in those with an H-Q interval ≥100 ms. These patients, when symptomatic, should clearly undergo prophylactic pacemaker insertion.

Available data suggest 2 subgroups of patients with bundle branch block at very high risk for spontaneous trifascicular block. One group includes those with atrial pacing-induced infranodal block as described by Dhingra et al,[19] and the other is of patients with an H-Q interval ≥100 ms. Either of these findings is of great clinical value but unfortunately is only found in a miniscule percentage of patients with bundle branch block. Clearly, more effective means are required to identify patients with bundle branch block at high risk for second or third degree AV block or sudden death. For example, if sudden death is related to malignant ventricular arrhythmias, then perhaps Holter monitoring or ventricular stimulation studies[24] or both will prove of value in the detection of a subset of patients with bundle branch block and transient symptoms who are at increased risk for this complication.

Effects of Verapamil on the Electrophysiologic Properties of the Accessory Pathway in Patients With the Wolff-Parkinson-White Syndrome

RICHARD W. HARPER, FRACP, ERIC WHITFORD, FRACP, KEN MIDDLEBROOK, SRN, JACK FEDERMAN, FRACP, STAN ANDERSON, FRACP, and AUBREY PITT, FRACP

The effects of intravenous verapamil on the electrophysiologic properties of the accessory pathway in 12 patients with symptomatic Wolff-Parkinson-White syndrome were studied using intracardiac electrical recordings. In 11 of the 12 patients it was possible to induce a reentrant supraventricular tachycardia with programmed atrial or ventricular pacing. After verapamil it was still possible to induce supraventricular tachycardia in 6 of the 11 patients; however, the mean cycle of length of the tachycardia increased from a control value of 330 ± 20 ms (mean ± standard error of mean) to 369 ± 21 ms ($p < 0.05$). Although verapamil had no significant effect on the anterograde refractory period of the accessory pathway as measured by the extrastimulus technique, it significantly increased maximal 1:1 atrioventricular (AV) conduction through the accessory pathway to incremental high rate atrial pacing in 10 of the 12 patients (control value 227 ± 10 beats/min, value after verapamil 258 ± 14 beats/min, $p < 0.001$). In 4 patients in whom episodes of atrial fibrillation could be compared before and after verapamil, the drug decreased the average R-R interval from a control value of 327 ± 27 ms to 282 ± 28 ms ($p < 0.05$) and decreased the shortest R-R interval between preexcited beats from a control value of 237 ± 21 ms to 209 ± 18 ms ($p < 0.05$).

It is concluded that in patients with symptomatic Wolff-Parkinson-White syndrome, verapamil may increase the ventricular response through the accessory pathway if atrial fibrillation occurs. This finding, which is of potential clinical significance, could not have been predicted from conventional anterograde refractory period estimations.

The calcium antagonist verapamil has proved an effective agent in the acute treatment of episodes of paroxysmal supraventricular tachycardia.[1–5] The drug is also sometimes used to prevent paroxysmal arrhythmias in patients with the Wolff-Parkinson-White syndrome. Despite its wide clinical use, uncertainty still exists regarding the safety of the drug in patients with this syndrome. Spurrell et al[6] reported that verapamil either lengthened or had no significant effect on the anterograde refractory period of the accessory pathway in 7 of 8 patients with the Wolff-Parkinson-White syndrome. In the remaining patient the refractory period decreased 35 ms. On this basis they concluded that verapamil was a safe drug to use in the majority of patients with Wolff-Parkinson-White syndrome. However, Henning et al[7] recently reported that verapamil increased the ventricular response to electrically induced atrial fibrillation in 7 patients with the Wolff-Parkinson-White syndrome and predominant conduction through the accessory pathway.

The purpose of this study was to assess the effects of verapamil on the electrophysiologic properties of the accessory pathway in patients with symptomatic Wolff-Parkinson-White syndrome. In particular, we evaluated the effect of the drug on maximal 1:1 atrioventricular (AV) conduction through the accessory pathway to incremental high rate atrial pacing and compared these results with those obtained by the conventional extrastimulus technique of measuring refractoriness.

AF = atrial fibrillation; AP= accessory pathway; AT = antidromic tachycardia (see text); C = control; ERP = effective refractory period; Left = left free wall; Max = maximal; PSVT = paroxysmal supraventricular tachycardia; Right = right free wall; Sept = septal; SVT = supraventricular tachycardia; V = verapamil.

priate clinical details, indications for the electrophysiologic study, and sites of the accessory pathway are shown in Table I.

All patients had evidence of preexcitation on at least 1 baseline 12-lead electrocardiogram. In 2 patients the accessory pathway was located in the septal region, 3 patients had right free wall pathways, and 7 patients had left free wall pathways. In 7 patients the indication for study was recurrent episodes of supraventricular tachycardia with narrow width QRS complexes during the tachycardia. In 4 patients the indication for study was paroxysmal atrial fibrillation. The remaining patient (Patient 7) had episodes of regular width QRS complex tachycardia (rate 200 beats/min) with the QRS complexes during the tachycardia identical morphologically to the delta wave.

Electrophysiologic studies: Patients were studied in the postabsorptive, nonsedated state after informed written consent was obtained. All antiarrhythmic therapy was discontinued for at least 72 hours before the study. Three quadripolar electrode catheters and 1 tripolar electrode catheter were introduced from 1 or both femoral veins and from a left antecubital vein. The tripolar catheter was used to record His bundle electrograms. One quadripolar catheter was positioned at the high lateral right atrium for stimulation and recording of high right atrial electrical activity. One quadripolar catheter was positioned at the apex of the right ventricle for stimulation and recording of right ventricular activity. The third quadripolar electrode catheter was used for recording and stimulation of the proximal and distal coronary sinus. All intracardiac electrocardiograms were recorded using a filter setting of 40 to 1,000 cycles/s. The intracardiac electrograms and lead II were recorded using a 6-channel Mingograph recorder with paper speeds between 25 and 200 mm/s.

Anterograde refractory periods of the AV node and accessory pathways were determined using the extrastimulus technique[8,9] at an atrial pacing interval of 500 ms (programmed atrial pacing). High rate atrial pacing was performed starting at an atrial pacing rate of 120 beats/min and gradually increasing the rate by approximately 10 beats every 15 seconds until block occurred in the accessory pathway (Fig. 1).

The right ventricular effective refractory period was determined using the extra stimulus technique at a basic pacing interval of 500 ms (programmed ventricular pacing). Incremental high rate ventricular pacing was performed starting at a pacing rate of 120 beats/min and increasing the rate by approximately 10 beats every 15 seconds up to a rate of 200 to 250 beats/min depending on the patient's clinical state or until ventriculoatrial block occurred. During programmed and incremental ventricular pacing, retrograde atrial conduction was carefully assessed.

During the anterograde and retrograde pacing studies, the ability to induce sustained supraventricular tachycardia and the cycle length of the induced tachycardia were noted. Retrograde accessory pathway conduction during supraventricular tachycardia was established by the presence of abnormal (eccentric) retrograde atrial activation and by the ability to prematurely capture the atria during supraventricular tachycardia with critically timed ventricular extra stimuli delivered when the His bundle was refractory.[10] Location of the accessory pathway was based on determination of the earliest site of retrograde atrial activation during supraventricular tachycardia and on analysis of the initial QRS vector of maximally preexcited beats during sinus rhythm or atrial pacing.[11]

Atrial fibrillation: Atrial fibrillation was not deliberately induced in this study; however, when arrhythmia occurred as a result of the pacing techniques, 12-lead electrocardiograms were recorded and the shortest interval between successive beats showing preexcitation (shortest R-R interval) and the average R-R interval over a 1 minute period were measured.

Verapamil administration: After control measurements were made, intravenous verapamil (dose 0.15 mg/kg) was given over a 5 minute period and the same electrophysiologic measurements were then repeated.

Definitions: The anterograde effective refractory period of the accessory pathway was defined as the longest atrial coupling interval (A_1–A_2) at which block occurred in the accessory pathway (disappearance of the delta wave).[8] Accessory pathway refractory periods were measured from the same site before and after administration of verapamil. The site was as close as possible to the accessory pathway.[8]

Maximal 1:1 AV conduction through the accessory pathway to incremental high rate atrial pacing was defined as the

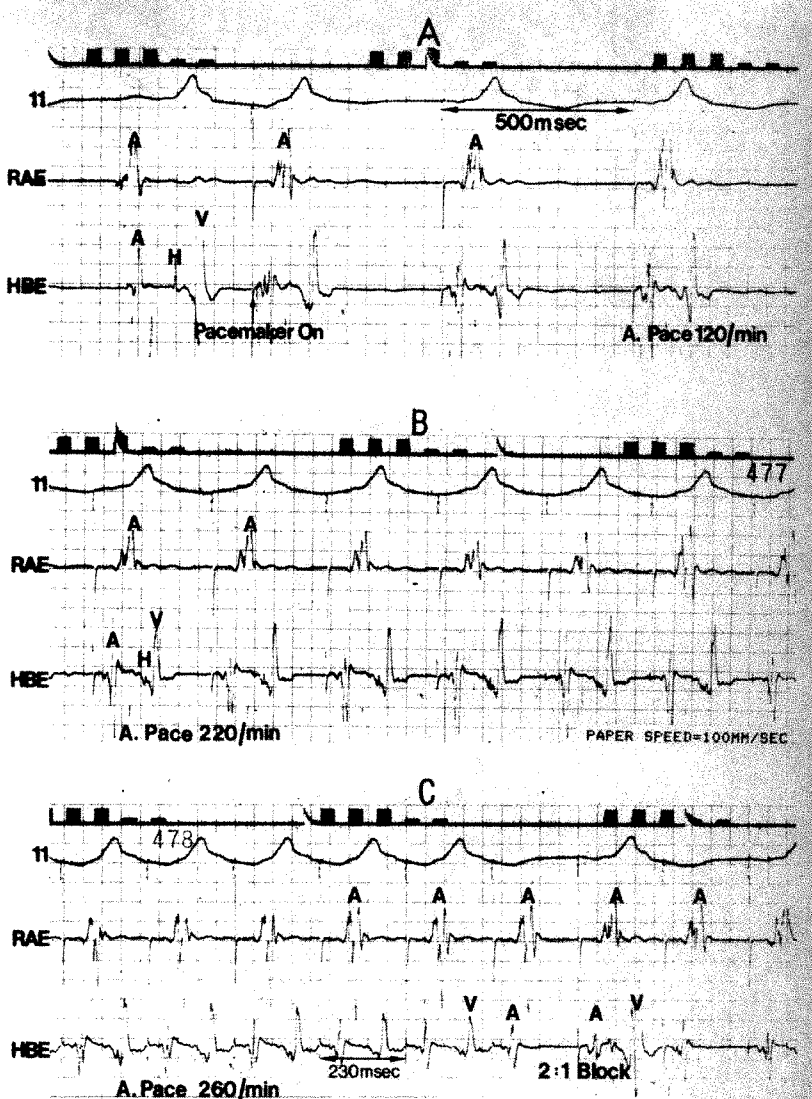

FIGURE 1. Technique of incremental high rate atrial pacing. **A,** commencement of atrial pacing at a rate of 120 beats/min. The first beat is a sinus beat with an abbreviated H-V interval due to preexcitation. **B,** atrial pacing has been increased to 220 beats/min with continued 1:1 conduction through the accessory pathway. **C,** at an atrial pacing rate just in excess of 260 beats/min (**arrow**), 2:1 block occurs in the accessory pathway. In this case, maximal 1:1 AV conduction through the accessory pathway is therefore 260 beats/min. In each panel, lead II, intracavity right atrial electrogram (RAE), and His bundle electrogram were recorded simultaneously. A = atrial activity; A.Pace = atrial pacing; H = His bundle activity; V = ventricular activity.

highest atrial pacing rate at which 1:1 anterograde (AV) conduction occurred through the accessory pathway. In our laboratory the coefficient of variation for duplicate measurements of this parameter is 2.1%.

The retrograde effective refractory period of the accessory pathway was defined as the longest ventricular coupling interval (V_1–V_2) at which the premature ventricular beat (V_2) failed to conduct to the atria through the accessory pathway.[8]

Maximal 1:1 ventriculoatrial (VA) conduction through the accessory pathway to incremental high rate ventricular pacing was defined as the highest ventricular pacing rate at which 1:1 VA conduction occurred through the accessory pathway.

Statistical analysis: Statistical analysis was performed using the 2-tailed *t* test for paired differences and 2-way analysis of variance.

Results

Anterograde properties of the accessory pathway (Table I): *The anterograde effective refractory period of the accessory pathway* could be measured in 9 of the 12 patients. In the remaining 3 patients (Patients 1, 2, and 8) atrial refractoriness precluded this measurement. The effective refractory period of the accessory pathway ranged from 220 to 310 ms (mean 283 ± 8 ms) during the control period and from 210 to 305 ms (mean 283 ± 10 ms) after the administration of verapamil (difference not significant [NS]).

Maximal 1:1 AV conduction through the accessory pathway to incremental high rate atrial pacing (Table I, Fig. 2) ranged from 180 to 290 beats/min (mean 227 ± 10) during the control period and from 170 to 330 beats/min (mean 258 ± 14) after the administration of verapamil ($p < 0.001$). Ten of the 12 patients showed an increase in maximal 1:1 AV conduction through the accessory pathway after verapamil. A typical response is shown in Figure 3. One patient (Patient 11) showed a decrease of 10 beats/min and 1 patient (Patient 4) had no change. The magnitude of the increase after verapamil tended to be greater in patients with the higher initial control values for this variable (Fig. 2).

Retrograde properties of the accessory pathway (Table I): Retrograde conduction through the accessory pathway could be demonstrated in 11 of the 12 patients

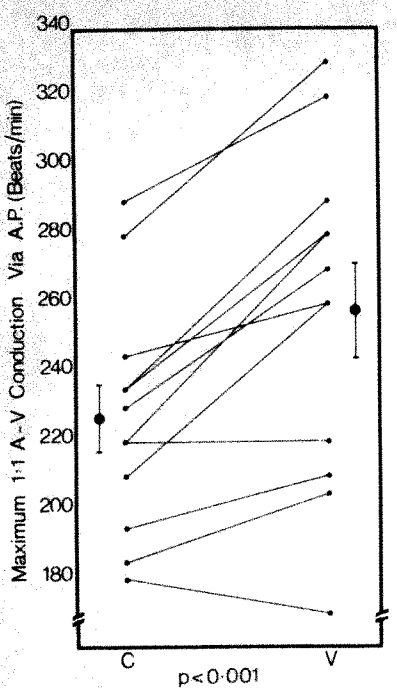

FIGURE 2. Effects of verapamil in each of the 12 patients on maximal 1:1 AV conduction through the accessory pathway during incremental high rate atrial pacing. Control (C) values are shown on the **left**, post-verapamil (V) values on the **right**. Mean values and standard error of the mean are shown. A.P. = accessory pathway.

before and after verapamil; no retrograde conduction could be demonstrated in Patient 9. The retrograde effective refractory period of the accessory pathway could be measured in only 4 patients (Table I). In the remaining 7 patients the functional ventricular refractory period exceeded the effective retrograde refractory period of the accessory pathway. In the 4 patients in whom this measurement could be obtained the mean control value was 258 ± 7 ms and the value after verapamil 253 ± 8 ms (NS).

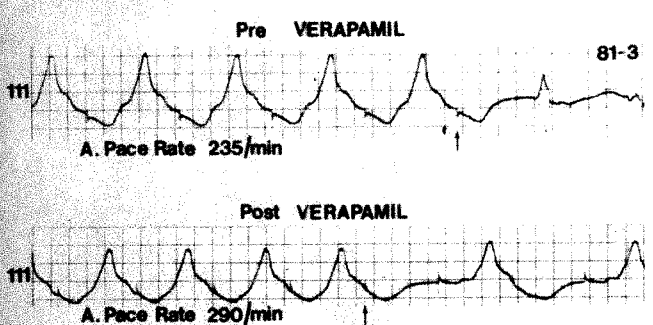

FIGURE 3. Patient 6. Typical effect of verapamil on maximal 1:1 AV conduction through the accessory pathway. The control value for this variable is 235 beats/min. At a slightly faster atrial pacing rate, block occurs in the accessory pathway (**arrow**) and a supraventricular beat due to exclusive conduction through the AV node ensues. Post verapamil, maximal 1:1 AV conduction through the accessory pathway increases to 290 beats/min. At a slightly faster atrial pacing rate, 2:1 block in the accessory pathway (**arrow**) occurs. III = lead III.

In 9 of the 11 patients retrograde conduction through the accessory pathway occurred during incremental high rate ventricular pacing up to the maximal tested rates (200 to 250 beats/min) (Table I). In 1 patient (Patient 3) the maximal rate of retrograde conduction through the accessory pathway increased from a control value of 205 to the highest tested rate of 220 beats/min after verapamil. In another patient (Patient 12) the rate increased from a control value of 235 to the maximal tested rate of 250 beats/min after verapamil.

Supraventricular tachycardia (Table I): Sustained supraventricular tachycardia could be induced by programmed pacing in 11 of the 12 patients before verapamil but in only 6 patients after verapamil. Ten of the 11 patients exhibited a typical "orthodromic" circus movement tachycardia with anterograde conduction through the AV node and His bundle and retrograde conduction through the accessory pathway.[11,12] One patient (Patient 7) exhibited both orthodromic supraventricular tachycardia and "antidromic" circus movement tachycardia.[11,12] In the latter instance, anterograde conduction occurred through the accessory pathway and retrograde conduction through the His bundle and AV node. After verapamil, supraventricular tachycardia could only be induced in 6 patients (Table I). In those 6 patients the tachycardia cycle length varied from 295 to 430 ms (mean 330 ± 20) before verapamil, and after verapamil the cycle lengths varied from 320 to 465 ms (mean 369 ± 21) ($p < 0.02$). The longer cycle lengths after verapamil reflected an increase in AV nodal conduction time (increase in A-H interval).

Atrial fibrillation (Table II): Atrial fibrillation resulted from high rate atrial pacing in 2 patients during the control period (Patients 5 and 8) and in 5 patients after verapamil (Patients 2, 5, 7, 8, and 9). In all instances atrial fibrillation occurred after a short period of block in the accessory pathway (Fig. 4). In cases 5 and 8 atrial fibrillation induced during the control period reverted spontaneously to sinus rhythm without drug therapy or electrical reversion. After verapamil, however, Patients 5, 8, and 9 required electrical reversion to restore sinus rhythm.

In Patients 2 and 9 in whom atrial fibrillation only occurred after verapamil, previously documented epi-

TABLE II Findings in Atrial Fibrillation*

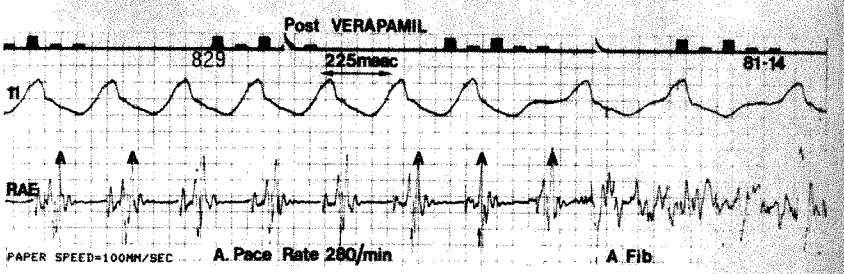

FIGURE 4. Patient 5, after verapamil. Induction of atrial fibrillation (A Fib) during incremental high rate atrial pacing. At an atrial pacing rate just in excess of 280 beats/min, a short period of 2:1 block in the accessory pathway (**arrow**) occurs and is followed by atrial fibrillation. Abbreviations as in Figure 1.

sodes of atrial fibrillation that had occurred when the patients were receiving no drug therapy were used for comparison with the postverapamil results. In the remaining case (Patient 7) in which atrial fibrillation only occurred after verapamil, no previous electrocardiogram during atrial fibrillation was available for comparison. Nine episodes of atrial fibrillation were therefore available for analysis. In all cases conduction during atrial fibrillation occurred exclusively or predominantly through the accessory pathway.

The average and the shortest R-R intervals during atrial fibrillation and after verapamil are shown in Table II. In these 5 patients the shortest R-R intervals during atrial pacing at which 1:1 AV conduction occurred through the accessory pathway are also shown in Table II. This latter measurement corresponds to the maximal atrial pacing rate at which 1:1 AV conduction occurred through the accessory pathway.

In the 4 patients in whom episodes of atrial fibrillation could be compared before and after verapamil, the average and the shortest R-R intervals were always shorter after verapamil (Table II). The mean average R-R interval was 327 ± 27 ms before and 282 ± 28 ms after verapamil ($p < 0.05$). The mean shortest R-R interval was 237 ± 21 ms before and 209 ± 18 ms after verapamil ($p < 0.05$). An example of atrial fibrillation before and after verapamil is shown in Figure 5.

A comparison between the shortest R-R intervals (y) during the 9 episodes of atrial fibrillation and the shortest R-R interval (x) at which 1:1 AV conduction occurred through the accessory pathway during incremental atrial pacing is shown in Figure 6. The correlation between these 2 variables was strong ($r = 0.95$). The regression equation was $y = 0.97x - 8.74$.

Discussion

Supraventricular tachycardia: The most common arrhythmia in patients with the Wolff-Parkinson-White syndrome is a paroxysmal circus movement (reentrant) tachycardia involving anterograde conduction through the AV node His bundle system and retrograde conduction through the accessory pathway (orthodromic supraventricular tachycardia).[11] Drugs such as verapamil that increase AV node refractoriness can terminate such arrhythmias and perhaps prevent their occurrence. Numerous investigators have demonstrated the effectiveness of an intravenous injection of verapamil in terminating spontaneous or induced episodes of supraventricular tachycardia.[1–5] Termination usually occurs as a result of block in the anterograde limb of the reentrant circuit (AV node).[1–5]

Recent reports suggest that the electrophysiologic response to acute intravenous drug administration accurately predicts the future response to oral adminis-

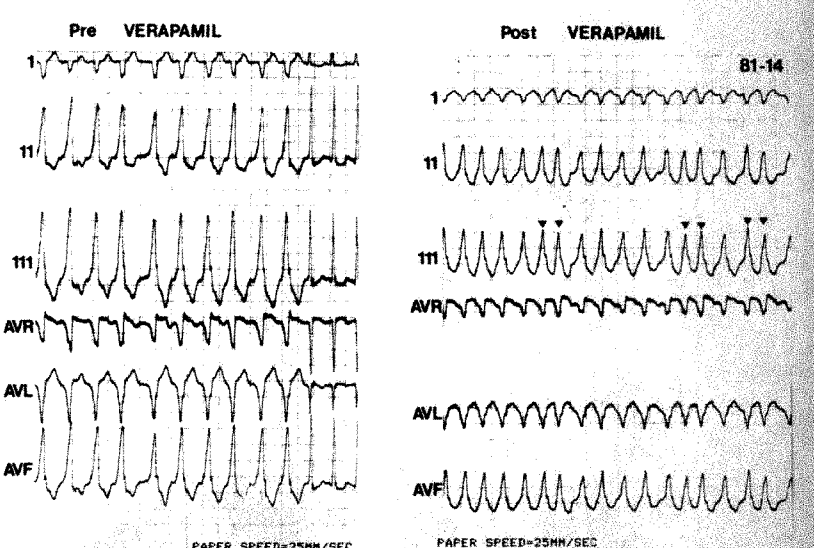

FIGURE 5. Patient 5. Six-lead electrocardiogram during atrial fibrillation before and after verapamil. The 6 leads are recorded simultaneously. The postverapamil electrocardiogram is recorded at half standard calibration. Note that post verapamil the average ventricular response is 240 beats/min, with all beats showing evidence of preexcitation. Several R-R intervals (**arrows**) are 200 ms in duration. Before verapamil the average ventricular response is 180 beats/min and some beats show exclusive conduction through the AV node.

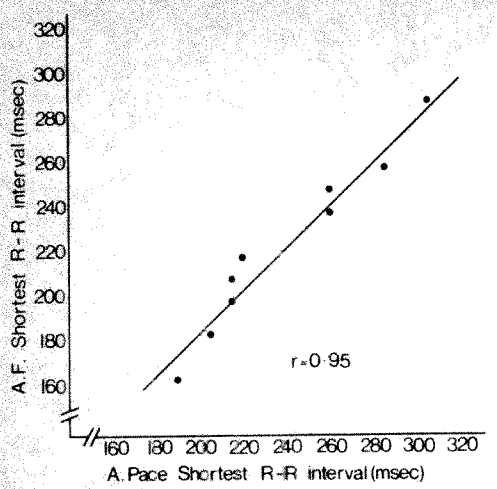

FIGURE 6. Relation between the shortest R-R interval during atrial fibrillation and the shortest R-R interval with 1:1 AV conduction through the accessory pathway during incremental high rate atrial pacing (A.Pace). Data from 9 episodes of atrial fibrillation are shown. The regression line is indicated.

tration of the same drug.[13] Some recent data suggest that this supposition may also be true for verapamil.[14] In our study it was still possible with programmed stimulation to induce episodes of supraventricular tachycardia in 6 of the 11 patients after a conventional dose of intravenous verapamil, although the tachycardia was invariably slower and sometimes terminated spontaneously. Of the 7 patients in whom orthodromic supraventricular tachycardia was the presenting problem, it was still possible to induce the tachycardia in 5 after intravenous verapamil. These results are similar to those reported by other investigators. Wellens et al[15] were still able to induce supraventricular tachycardia after intravenous verapamil in 3 of 3 patients with accessory pathways. Rinkenberger et al[5] were able to induce supraventricular tachycardia in 4 of 6 patients with the Wolff-Parkinson-White syndrome after intravenous verapamil.

The apparent discrepancy between the ability of verapamil to terminate an episode of supraventricular tachycardia and its inability to always prevent further induction of this arrhythmia is presumably related to differences between the immediate and the steady state effects of the drug. By producing an abrupt increase in AV node refractoriness, intravenous verapamil results in a sudden block in the AV node and therefore termination of the supraventricular tachycardia. Once a new equilibrium has been achieved in the AV node, it is often still possible to induce reentrant supraventricular tachycardia, albeit at a slower rate because of increased conduction time through the AV node.

On the basis of the acute results of this and other studies,[5,15] it seems likely that oral verapamil, when given alone in conventional doses, will not prevent episodes of supraventricular tachycardia in many patients with symptomatic Wolff-Parkinson-White syndrome.

Atrial fibrillation: When atrial fibrillation occurs in the Wolff-Parkinson-White syndrome, the ventricular response is largely determined by the anterograde properties of the accessory pathway.[16–20] If the refractory period is short, the ventricular response will be rapid and hemodynamic embarrassment or even ventricular fibrillation may occur.[11,21] Studies show that the risk of ventricular fibrillation is greatest when the mean ventricular response is fast and when the shortest interval between successive beats is 200 ms or less.[11,20] Drugs such as digoxin which sometimes shorten the refractory period of the accessory pathway may increase the risk of ventricular fibrillation.[20–23]

In this study verapamil significantly increased the maximal 1:1 AV conduction through the accessory pathway to incremental high rate atrial pacing in 10 of the 12 patients by an average of 31 beats/min. This effect of verapamil was more pronounced in patients with relatively fast control values for this variable. In 4 patients in whom episodes of atrial fibrillation could be compared, the ventricular response was always faster and the shortest R-R interval always shorter after verapamil. The foregoing findings strongly suggest that verapamil is likely to increase the ventricular response to spontaneous atrial fibrillation in patients with the Wolff-Parkinson-White syndrome and in some the consequences could be dangerous. Other investigators have reported similar findings.[5,7,24] Henning et al[7] reported on 7 patients with the Wolff-Parkinson-White syndrome and predominant conduction through the accessory pathway in whom verapamil increased the ventricular response to induced atrial fibrillation by an average of 30 beats/min and decreased the shortest R-R interval from a mean of 237 ms to a mean of 199 ms. Gulamhusein et al[24] reported that verapamil increased the ventricular response to induced atrial fibrillation in 4 of 8 patients with the Wolff-Parkinson-White syndrome. These investigators noted that patients with predominantly preexcited QRS complexes during atrial fibrillation appeared more likely to have acceleration of ventricular response than patients with predominantly normally conducted QRS complexes.

It could be argued that verapamil might prevent episodes of atrial fibrillation in patients with the Wolff-Parkinson-White syndrome either by altering the electrophysiologic properties of atrial muscle or by preventing or reducing the rate of reentrant supraventricular tachycardia. If this were so then the findings in this study would be of academic rather than practical significance. To our knowledge, however, there have been no studies that have specifically addressed this problem nor is there convincing evidence that verapamil prevents atrial fibrillation in other conditions associated with this arrhythmia. In our study atrial fibrillation during incremental high rate atrial pacing occurred more frequently after verapamil than during control measurements, but this probably was a reflection of the faster atrial pacing rates achieved after verapamil rather than any tendency of the drug to precipitate this arrhythmia. An associated observation was that both

episodes of atrial fibrillation during the control period reverted spontaneously whereas 3 of the 5 episodes after verapamil required electrical cardioversion. Similar findings were noted by Gulamhusein et al.[24] Until further information is available it would seem prudent to consider that verapamil may not prevent episodes of atrial fibrillation in patients with the Wolff-Parkinson-White syndrome and is likely to increase the ventricular response through the accessory pathway should this arrhythmia occur.

Possible mechanisms whereby verapamil could affect conduction of atrial impulses through the accessory pathway: Several mechanisms are possible. First, the drug could exert a direct effect on the cells of the accessory pathway. In the cat atria, verapamil decreases the action potential duration and increases the conduction velocity to rapid stimuli.[25] Hasin and Rogel[26] showed that verapamil slightly increases conduction velocity in the ventricular myocardium of the dog. If, as it seems likely, the accessory pathway is made up of either atrial or ventricular myocardium, verapamil could be expected to exert a similar effect and thus facilitate conduction.

A second means by which verapamil could indirectly influence anterograde conduction through the accessory pathway is its effect on the AV node. By slowing or blocking conduction of atrial paced beats or atrial fibrillation impulses in the AV node,[27] verapamil could reduce the degree of concealed retrograde penetration of the accessory pathway and thereby decrease anterograde refractoriness. A similar mechanism has been postulated to explain the increased ventricular response to atrial fibrillation after digoxin[22,23] in some patients with the Wolff-Parkinson-White syndrome.

Third, verapamil, by reducing blood pressure, may have reflexly increased sympathetic tone and thereby possibly altered conductivity and refractoriness of the accessory pathway.[28] Although both intravenous and oral verapamil will cause vasodilation and reduction of blood pressure, the effects of intravenous verapamil on sympathetic tone may be more pronounced than those of oral verapamil. We are therefore unable to say whether oral verapamil would have the same effects as intravenous verapamil on the ventricular response in atrial fibrillation.

Relation between refractory period estimation and response to high rate atrial pacing: An important finding in this study is that the effect of verapamil on the response to high rate atrial pacing could not have been predicted by the anterograde refractory period estimation of the accessory pathway. In this study, as in the study of Spurrell et al,[6] verapamil had no significant effect on the anterograde refractory period of the accessory pathway as determined by the extra stimulus technique. There are several possible reasons for the apparent discrepancy between the results of the refractory period estimation and the results of incremental high rate atrial pacing. Refractoriness of cardiac tissue is strongly influenced by heart rate.[29] A refractory period estimation at a pacing rate of 120 beats/min, as in this study, may not necessarily predict the refractory period response at atrial pacing rates of 200 beats/min or more. Furthermore, it is often impossible to estimate the anterograde effective refractory period of the accessory pathway because this determination may be limited by refractoriness of the atrial muscle,[8,11,20] as was the case in 3 of our patients. Finally, estimation of the effective refractory period may be influenced by relative differences in intraatrial conduction between the basic paced beat and the premature beat.[8,11] By altering atrial conduction, the true effects of a drug on the refractory period of the accessory pathway may be masked.[8,11] This problem will be minimized but not necessarily completely prevented by recording atrial electrograms close to the presumed site of the accessory pathway. In several studies the correlation between the accessory pathway refractory period and the shortest R-R interval during atrial fibrillation was relatively weak.[20,30]

In view of these difficulties with refractory period estimation, we believe that incremental high rate atrial pacing, which more closely simulates atrial flutter and fibrillation, is a preferable means of determining the likely effect that a drug will have on these tachyarrhythmias in patients with the Wolff-Parkinson-White syndrome. In our study there was a strong correlation between the shortest R-R interval achieved during atrial pacing and the shortest R-R interval during atrial fibrillation with a tendency for the former measurement to slightly overestimate the latter.

Clinical implications: The results of this study suggest that verapamil is likely to be of limited value in preventing episodes of supraventricular tachycardia in patients with the Wolff-Parkinson-White syndrome. More importantly, the drug may possibly increase the ventricular response to spontaneous atrial fibrillation with potentially dangerous consequences in patients who already have a fast response. For these reasons we believe that long-term verapamil therapy should be avoided in patients with the Wolff-Parkinson-White syndrome unless an electrophysiologic study has demonstrated its safety. The findings in this study do not detract from the usefulness of intravenous verapamil in terminating episodes of supraventricular tachycardia, providing the drug is administered under appropriate cardiac monitoring.

Acknowledgment: We express our gratitude to the staff of the cardiology laboratory for their help in the electrophysiologic studies, to Lyn Sawyer, who prepared the illustrations, and to Barbara Hudspith, who prepared the manuscript.

Atrial Excitability and Conduction in Patients With Interatrial Conduction Defects

ROSS J. SIMPSON, Jr., MD, JAMES R. FOSTER, MD, and LEONARD S. GETTES, MD

Prolongation of P-wave duration is an accepted indicator of an interatrial conduction disturbance and may predispose patients to atrial arrhythmias. This study was performed to monitor electrophysiologic characteristics of the atria in patients with a prolonged P-wave duration. Atrial excitability and conduction times were compared in 7 patients with a P-wave duration <115 ms (Group I) and 13 patients with a duration ≥115 ms (Group II). In contrast to the Group I patients, most of the 13 patients in Group II had atrial arrhythmias, including sinus nodal dysfunction (3 patients) and a history of atrial fibrillation or ectopic atrial tachycardia (6 patients). Electrophysiologic differences between the 2 groups included a higher late diastolic threshold in Group II (0.8 ± 0.2 mA versus 1.3 ± 0.2 mA; p <0.005), and a greater increase in intraatrial conduction time (5 ± 10 ms versus 30 ± 20 ms; p <0.005) and interatrial conduction time (5 ± 15 ms versus 30 ± 15 ms; p <0.05) of early premature responses. There were no differences between the 2 groups in refractory periods, shape of the strength interval curve, or conduction times of premature responses occurring late in diastole.

These abnormalities in conduction time and excitability found in patients with a prolonged P-wave duration may predispose to the initiation of certain atrial tachyarrhythmias.

Human atrial tissue taken from patients with an enlarged atrium and a history of atrial tachyarrhythmias demonstrates abnormalities of the action potential that could, and probably would, alter conduction and excitability of the atrium, and create vulnerability to reentrant arrhythmias. Resting membrane potential is elevated, and the maximal amplitude of the action potential and upstroke velocity is depressed.[1-9] Given these known cellular abnormalities, we should be able to detect abnormalities in conduction and excitability in similar patients by standard endocardial extrastimulus pacing and recording techniques.

We report herein the results of clinical electrophysiologic studies of the intact human atrium designed to detect such abnormalities in patients with atrial disease. We classified our patients on the basis of the P-wave duration on the electrocardiogram and compared atrial excitability and conduction time in patients with normal and prolonged P-wave durations. We looked particularly for differences in conduction time of premature atrial responses in patients with a prolonged P-wave duration that might explain the propensity of early premature atrial beats to act as a trigger for the initiation of repetitive atrial beats or atrial fibrillation.

Methods

Twenty consecutive patients, 11 men and 9 women aged 28 to 84 years who were in sinus rhythm, were studied. Cardioactive drugs were discontinued at least 72 hours before the procedure, and informed consent was obtained. The research procedure followed a clinical electrophysiologic study performed to evaluate sinus nodal dysfunction, atrioventricular conduction disturbances, supraventricular arrhythmias, or ventricular arrhythmias. Seven patients had atherosclerotic heart disease, 5 had hypertensive cardiovascular disease, and 1 had primary myocardial disease. Seven patients had no obvious organic heart disease. All patients with organic heart disease were in New York Heart Association[10] class I or II for congestive failure.

The patients were classified into 2 groups depending on the P-wave duration. The P wave was the average duration of 10 consecutive sinus beats from lead II of the electrocardiogram recorded during the electrophysiologic study at a paper speed of 250 mm/s. The P-wave duration and the appropriateness of the classification of each patient into Group I or II was confirmed by measuring the maximal duration of the P wave with vernier calipers from the standard electrocardiogram, magnified approximately 2.5 times by projection on an opaque screen.

In 7 patients the P-wave duration was <115 ms. These patients comprised Group I. In 13 patients, the P-wave duration was ≥115 msec. These patients comprised Group II. There was no significant difference between the 2 groups in sex distribution or in the type of underlying organic heart disease. Although the incidence of symptomatic congestive heart failure was greater in Group II, this difference did not achieve significance. Patients in Group II tended to be older (p <0.05) and to have undergone the electrophysiologic study for evaluation of sinoatrial or atrioventricular conduction abnormalities (p <0.06) (Table I).

TABLE I Clinical Characteristics

	Group I P<115 ms (7 Patients)	Group II P ≥115 ms (13 Patients)
Age (yr)	53 ± 16	65 ± 13
Organic heart disease	5	8
NYHA functional class II	1	5
Reason studied		
SA or AV block	2	10
SVT	2	2
VT	3	1

AV = atrioventricular; NYHA = New York Heart Association; SA = sinoatrial; SVT = supratricular tachycardia; VT = ventricular tachycardia.

Atrial excitability and conduction during early and late diastole were measured by the endocardial extrastimulus technique. Standard quadripolar catheters with an interelectrode separation of 1 cm were positioned in the high lateral right atrium by way of the right femoral vein. Atrial pacing was performed through the distal pair of electrodes and local atrial activation was recorded through the proximal pair of electrodes. In 16 patients catheters were positioned in the low septal right atrium to record a His bundle deflection. Left atrial activity was measured from the distal coronary sinus in 7 patients, the pulmonary artery in 2 patients, the lateral left atrium in 1 patient, and the mid-coronary sinus in 1 patient.[11] Since we were primarily interested in observing the change in conduction time of early compared with late premature atrial beats rather than in measuring conduction times to specific left atrial recording sites, and since each patient served as his (or her) own control, we treated these multiple left atrial recording sites as a single one (A_{LA}) in our analysis. The intracardiac electrograms were filtered through a band of 50 to 500 Hz.

The position of the high right atrial catheter was adjusted under fluoroscopy until a late diastolic threshold of <1 mA was obtained. If this could not be accomplished despite multiple changes in position and stimulus polarity, the catheter position and polarity that allowed the lowest stable late diastolic threshold was used. A stimulator designed by M. Bloom and Associates (Philadelphia, Pennsylvania) or one designed in our laboratory,[12] provided the drive (S_1) and premature (S_2) stimuli. The current strength of the stimulus was measured by a calibrated voltage-to-current converter and the voltage was displayed simultaneously with standard electrocardiographic leads I, II, and VI and with the intracardiac electrograms on a VR12 Electronics for Medicine recorder. Events were preserved on photographic paper at a speed of 100 to 250 mm/s and on magnetic tape for later review. The S_1 and S_2 stimuli were 2 ms in duration and were delivered from the same pair of electrodes. The current strength of the S_1 stimuli was held constant at twice the late diastolic threshold.

After 8 to 10 beats of drive pacing (S_1) at a cycle length of 600 ms (19 patients) or 500 ms (1 patient), a premature stimulus (S_2) was delivered. The current of the premature stimulus was decreased by 0.1 mA until it failed to induce a propagated response. The minimum current necessary to elicit a propagated atrial response was defined as the threshold at that S_1–S_2 coupling interval. The S_1–S_2 interval was decreased by 10 ms decrements during early diastole and the current of the S_2 increased as needed until a premature stimulus of 10 times the diastolic threshold failed to initiate a propagated response.

Definitions: The *effective refractory period* was defined as the longest S_1–S_2 interval at which a stimulus of 10 mA failed to initiate a propagated response. The *functional refractory period* was defined as the shortest attainable A_1–A_2 interval. The *total refractory period* was the S_1–S_2 interval at which the threshold assumed a steady level that was maintained for the remainder of the cardiac cycle. The *relative refractory period* was the difference between the effective and total refractory periods. The *late diastolic threshold* was the average threshold following the end of the total refractory period. These definitions were developed in previous experiments in man and in intact animals.[13]

Sinus echo beats were defined as spontaneous, premature A_3 responses having a P-wave configuration and activation sequence similar to the normal sinus beat and occurring before the line of interpolation.[14] *Repetitive atrial firing* was defined as 2 or more spontaneous atrial responses with an A_2–A_3 cycle ≤250 ms and subsequent A_3–A_4 cycles ≤300 ms.[15]

The conduction time from the S_2 stimulus to the first high amplitude, high frequency deflection of each of the recording catheters was measured at the threshold current for each S_1–S_2 interval. During the relative refractory period the amplitude and frequency of local electrograms tended to decrease in most patients. When this occurred, measurements were made to the first high frequency deflection that was reproducible on preceding and subsequent S_1–S_2 test intervals and clearly distinguishable from the baseline. The *intraatrial conduction time* (A_{HRA}–A_{HIS}) was obtained by subtracting the time delay of the stimulus artifact of the high right atrial electrogram (S–A_{HRA}) from the time delay of the stimulus to the low septal right atrial electrogram (S–A_{HIS}). The *interatrial conduction time* was measured in a similar manner using the left atrial and high right atrial electrograms (A_{HRA}–A_{LA}). Strength-interval and conduction-interval curves were constructed by plotting threshold current and conduction time as a function of S_1–S_2 or A_1–A_2 intervals.

The late diastolic threshold was measured from the high right atrial catheter at the beginning and the end of the strength-interval measurements. If catheter position changed or an unexpected change in threshold occurred, the catheter was repositioned and the study repeated.

The *maximal sinus nodal recovery time* was measured in 18 patients by the method described by Dhingra et al.[16]

Statistical methods: Differences between groups are expressed as the mean ±1 standard deviation. Significance was analyzed by the 2-sample *t* test, or by Fisher's exact test when appropriate.

The relation between conduction time and threshold was analyzed as a growth curve. For each patients, the threshold at all S_1–S_2 coupling intervals was normalized to the late diastolic threshold. The Mann-Whitney test was applied to the median conduction times of arbitrarily assigned overlapping intervals of the current threshold.

Results

Table II presents the P-wave duration, the late diastolic threshold, the maximal change in conduction time, and the arrhythmia history of each patient. Sinoatrial block or other electrocardiographic characteristics of the sick sinus syndrome[17] were present in 7 Group II patients and in 1 Group I patient. The sinus nodal recovery time was normal in all patients in Group I but was prolonged in 3 patients in Group II. Paroxysmal supraventricular tachycardia caused by reentry within the atrioventricular node in 2 patients in Group I, sustained atrial fibrillation in 5 patients in Group II, and ectopic atrial tachycardia in 1 patient in Group II had been documented before the study. No patient in

TABLE II P-Wave Duration, Diastolic Threshold, Change in Conduction Time and Atrial Arrhythmias

Patient	P-Wave Duration (ms)	Threshold (mA)	Maximal Increase (ms) in			Atrial Tachyarrhythmias

20	125	...	60	40	45	0	Echo

AF = atrial fibrillation; EAT = ectopic atrial tachycardia; ECHO = single sinus echo beat; RAF = repetitive atrial firing.

Group I had a history of atrial fibrillation, ectopic atrial tachycardia, or atrial flutter.

Refractory period, late diastolic threshold, and the atrial strength interval relationship: The effective, functional, total, and relative refractory periods of both groups were similar (Table III).

The late diastolic threshold was higher in patients in Group II (Fig. 1). Threshold increased at short S_1-S_2 intervals. For most patients, threshold increased continuously during the relative refractory period (Fig. 2). However, 1 patient in Group I and 3 patients in Group II demonstrated decreases of ≥20% below the late diastolic threshold before the effective refractory period. One additional Group II patient had an unexpected but less dramatic decrease in threshold that did not fall below the late diastolic value. This period when threshold was lower than in late diastole ranged from 25 to 125 ms and had a mean duration of 65 ± 30 ms.

We attributed this apparent "dip" in the excitability curve to stimulus polarity, since in each of 3 tested patients we were able to induce such a "dip" by reversing the polarity of the stimulating electrodes. In addition, reversing the polarity increased the late diastolic threshold by a small amount (0.2 to 0.3 mA) but did not change the effective refractory period and the intraatrial and interatrial conduction times.

TABLE III Refractory Periods

	Group I P <115 ms	Group II P ≥115 ms	p
Effective	235 ± 30	235 ± 45	NS
Functional	305 ± 25	295 ± 50	NS
Total	345 ± 45	345 ± 90	NS
Relative	105 ± 50	110 ± 55	NS

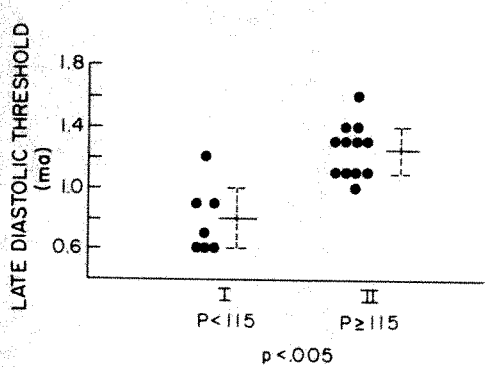

FIGURE 1. Late diastolic threshold in patients with a normal (Group I) and prolonged P-wave duration (Group II). The mean value in Group I was 0.8 ± 0.2 mA, with a range of 0.6 to 1.2. The mean value in Group II was 1.3 ± 0.2 mA, with a range of 1.0 to 1.6. This difference was significant ($p < 0.005$).

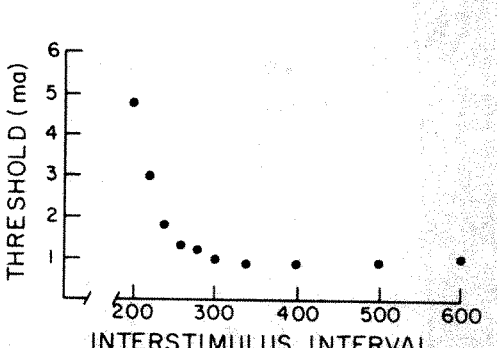

FIGURE 2. Atrial strength-interval curve from a patient from Group II with a P-wave duration of 118 ms. The interstimulus interval is the S_1-S_2 interval expressed in milliseconds.

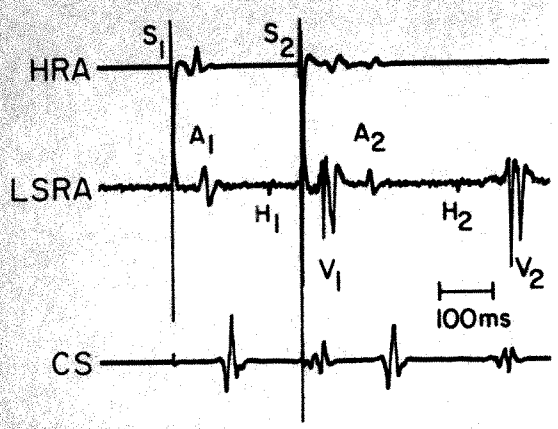

FIGURE 3. Intracardiac recordings from the high right atrium (HRA), low septal right atrium (LSRA), and distal coronary sinus (CS) in the patient discussed in Figure 2. At this S_1–S_2 coupling interval, the threshold has increased. The conduction time from the S_2 stimulus to the local electrograms of the HRA, LSRA, and CS catheters has increased, as have the conduction times from the local atrial electrogram of the HRA catheter to the local atrial electrograms of the LSRA and CS catheters. The paper speed was 100 mm/s. S_1 is the stimulus artifact of the nonpremature beat, A_1 is the response, H_1 is the His bundle deflection, and V_1 is the local ventricular electrogram. S_2, A_2, H_2, and V_2 refer to the premature response.

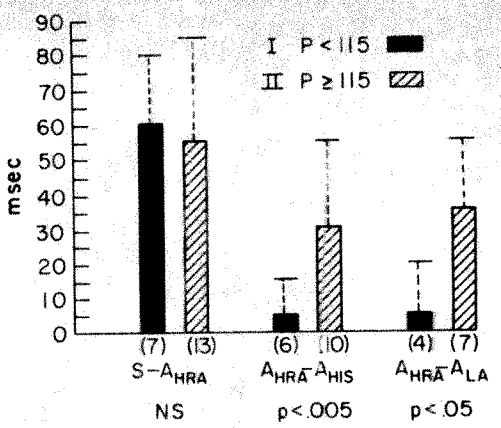

FIGURE 4. Maximal increase in latency (S–A_{HRA}), intraatrial (A_{HRA}–A_{HIS}), and interatrial (A_{HRA}–A_{LA}) conduction time of early premature responses induced during the relative refractory period. The intra- and interatrial conduction time increased significantly in Group II patients. There was no significant difference in S–A_{HRA} in the 2 groups. The **numbers in parentheses** represent the number of patients in whom the conduction time was measured.

Atrial conduction times of premature and nonpremature responses: For nonpremature responses or for premature responses induced at long S_1–S_2 coupling intervals, there was no significant difference in S–A_{HRA}, A_{HRA}–A_{HIS}, or A_{HRA}–A_{LA} for Groups I or II. However, a significant difference between the 2 groups developed as the S_1–S_2 interval was decreased and the relative refractory period was entered. This consisted of a greater increase in the intraatrial and interatrial conduction time in the Group II patients. Figure 3 is an example of the changes in conduction time of early atrial responses in a patient from Group II. During S_1–S_1 pacing, the conduction times are constant. During premature stimulation at short S_1–S_2 intervals, the S–A_{HRA}, A_{HRA}–A_{HIS}, and A_{HRA}–A_{LA} intervals increase.

Figure 4 shows the maximal increase in these conduction intervals of premature responses induced during the relative refractory period in all patients. S–A_{HRA} more than doubled in both groups, but there was no significant difference in the magnitude of the increase between the groups. In contrast, the increase in A_{HRA}–A_{HIS} and A_{HRA}–A_{LA} was significantly greater in Group II. Eleven of the 13 patients in Group II and 2 of the 7 patients in Group I had an increase >10 ms in interatrial or intraatrial conduction. Examples of the difference in early responses in the 2 groups are shown in Figure 5.

There was a direct correlation between the increase in intraatrial conduction time and the increase in interatrial conduction time. Seven patients had simultaneous measurements of both intraatrial and interatrial conduction. Stimulation at short S_1–S_2 intervals within the relative refractory period resulted in no change in either intraatrial or interatrial conduction in 3 patients,

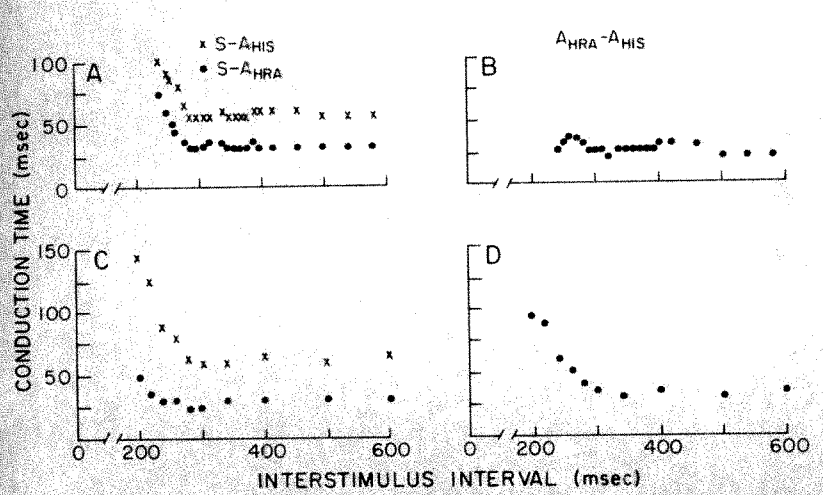

FIGURE 5. Examples of conduction-interval curves from 2 patients. **Panels A** and **B** are from a patient in Group I with a P-wave duration of 100 ms. **Panel A** is a graph of the conduction time from the stimulus to the local high right atrial electrogram (S–A_{HRA}) and from the stimulus to the local atrial electrogram of the low septal right atrial catheter (S–A_{HIS}). **Panel B** shows the intraatrial conduction time (A_{HRA}–A_{HIS}) determined by subtracting the latter 2 conduction intervals. As can be seen, there is little increase in A_{HRA}–A_{HIS}. **Panels C** and **D** are from the same patient described in Figure 2. A marked increase in intraatrial conduction time is seen.

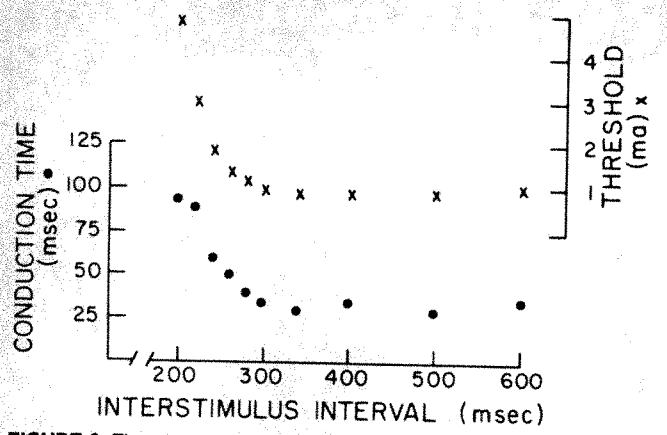

FIGURE 6. The strength-interval and conduction-interval curves from the patient described in Figure 2 are plotted on the same graph to show the simultaneous increase in intraatrial conduction time (A_{HRA}–A_{HIS}) and threshold.

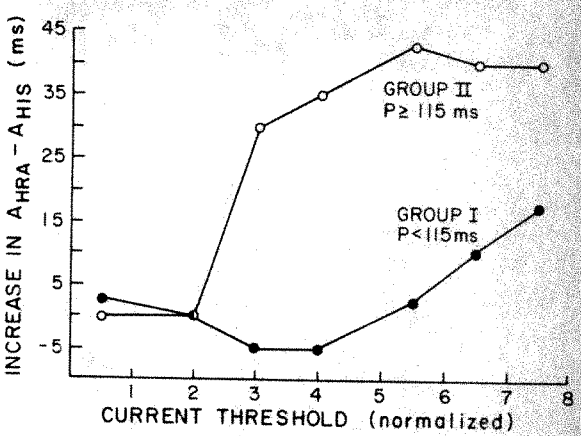

FIGURE 7. Relation of the increase in intraatrial conduction time (A_{HRA}–A_{HIS}) to threshold current. The threshold current was normalized by dividing the threshold at each S_1–S_2 interval by the late diastolic threshold for each patient. The points on the graph represent the change in the median conduction time plotted at the mid-point of intervals of the threshold current. Significant differences ($p < 0.01$) between the 2 groups in the change in conduction time are present at the mid-range of threshold currents.

a 50 ms increase in both conduction times in 1 patient, and a 20, 30, and 40 ms increase in intraatrial conduction associated with, respectively, a 25, 20, and 45 ms increase in interatrial conduction time in the 3 remaining patients. The correlation was significant (Spearman's $r = 0.96$, $p < 0.002$).

Relation between threshold and conduction time: Because of the difference in the conduction time of early premature responses in the 2 groups, the relation between threshold current and the increase in intraatrial and interatrial conduction also differed. In Group II, changes in conduction time tended to parallel the increase in threshold during the relative refractory period (Fig. 6). This did not occur in Group I. This difference in the relation between threshold current and intraatrial conduction is also shown in Figure 7.

To confirm that the increase in stimulus strength did not cause the increase in interatrial or intraatrial conduction, we tested the effect of a 2- to 3-fold increase in stimulus threshold during late diastole in 5 patients who demonstrated an increase in conduction time of the early premature response. This maneuver did not influence intraatrial or interatrial conduction time. Two of these patients had a small (10 ms) decrease in S–A_{HRA}.

Correlation with atrial arrhythmias: The ability to induce repetitive atrial firing or sinus echo beats was associated with the maximal increase in atrial conduction time ($p < 0.005$). Figure 8 illustrates the relation between the maximal conduction slowing in the premature response and the development of single or multiple spontaneous atrial responses. All 6 patients without conduction slowing in the premature response were in Group I. None had either single or multiple spontaneous response. The 2 patients with repetitive atrial firing had the greatest increase in interatrial conduction; both were in Group II. Five of the 6 patients with a >30 ms increase in intra- or interatrial conduction time had either repetitive atrial firing or sinus echo beats; the other patient had a history of recurrent lone atrial fibrillation. Figure 8 also shows that an increase in conduction time from 10 to 30 ms in the premature response was not predictive of a spontaneous response, since 4 of these patients had no such beats and 3 had only a single sinus echo beat.

All patients with either prolonged sinus node recovery times or a history of atrial fibrillation were in Group II. However, within this group there was no apparent correlation between the maximal increase in atrial conduction time, sinus nodal dysfunction, or the history of atrial fibrillation. There was no apparent correlation

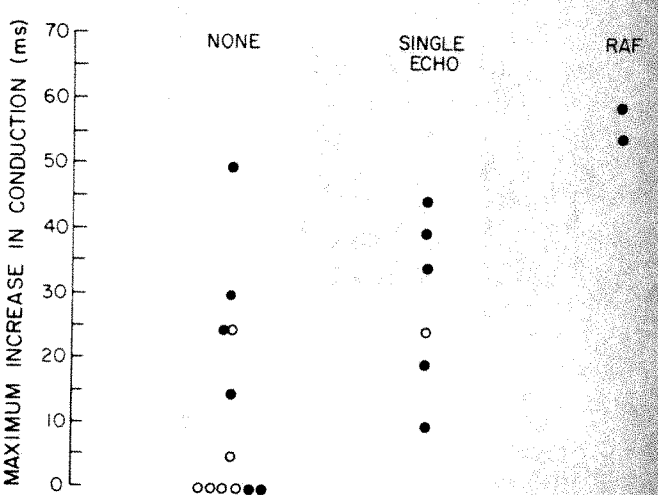

FIGURE 8. Relation between the change in intraatrial and interatrial conduction time and the initiation of single echo beats and repetitive atrial firing (RAF). Atrial conduction time refers to either intra- or interatrial conduction, depending on which measurement was available. If both conduction times were measured, the conduction time with the greatest change is shown. The **open circles** represent Group I patients and the **closed circles** Group II patients. The association between the increase in atrial conduction time and the induction of echo and repetitive atrial firing is significant ($p < 0.005$).

between historical atrial fibrillation and our ability to induce sinus echo beats or repetitive atrial firing.

Neither the shape of the atrial strength interval curve nor the duration of the atrial refractory periods was a correlate of induced echo beats or repetitive firing or of historical atrial fibrillation.

Discussion

Our results are consistent with those of single fiber studies performed in human atrial tissue removed at the time of cardiac surgery.[6–9] Fibers from the patients with an enlarged atrium, a prolonged P-wave duration, and a history of preoperative atrial arrhythmias had changes in the resting membrane potential, maximal velocity of the action potential upstroke, and the action potential amplitude, each of which are associated with depressed conduction velocity and depressed excitability.[6] These electrophysiologic abnormalities would explain the elevated late diastolic threshold we found in Group II patients. They are also consistent with the concept that a prolonged P-wave duration represents an interatrial conduction defect that can occur independently of an increase in atrial size.[18] The increased conduction slowing of the early premature response in our patients with interatrial conduction defects probably occurs because of further depression of conduction velocity of abnormal and already partly depressed atrial fibers.

However, although conduction slowing of early premature responses occurs primarily in the group with a prolonged P wave, the correlation between P-wave duration and conduction slowing of early premature responses was poor. Some patients with only slightly prolonged P-wave durations had a major increase in conduction time of early premature responses, while other patients with more marked P-wave durations had only minor increases in conduction time, It is unlikely that this apparent discrepancy reflects inaccurate measurement of P-wave durations since the P-wave duration was confirmed by 2 methods. Rather, it suggests that abnormalities in atrial conduction may exist in the absence of obvious changes of P-wave duration, and that a P wave >115 ms identifies patients with abnormalities in atrial conduction and excitability.

Previous studies of intact animal and normal human atria have demonstrated that atrial conduction times of very early premature beats may lengthen.[19–21] However, these studies did not attempt to separate the conduction slowing into that attributable to changes in latency occurring near the stimulating electrode and those caused by more distal conduction delays. This difference is important because changes in latency can be caused by changes in the strength of the stimulus and other factors. Increases in latency are not generally believed to be caused by depression of conduction velocity.[22]

Our study demonstrates that conduction time in patients with a diseased atrium and interatrial conduction defects during sinus rhythm may be further prolonged by premature stimulation during the relative refractory period. In our experiments $S–A_{HRA}$, which includes stimulus latency, increased in all of our patients and the amount of increase was similar in both the patients with a normal and prolonged P-wave duration. However, clear differences in intra- and interatrial conduction in the 2 groups of patients could be detected in the early atrial premature responses.

This difference in conduction time of the premature response is even more striking when seen in the light of the similarity in conduction time of the nonpremature beat in the 2 groups. We did not find the expected slightly longer inter- and intraatrial conduction times in the patients with prolonged P-wave durations, a fact that may be partly explained by the limitation of the P wave as a measurement of atrial conduction and, more importantly, by electrode positioning in our protocol. Being interested in the difference in conduction time of early and late premature beats, we did not attempt to measure the maximal intra- or interatrial conduction times. Catheters were positioned in the high right atrium to achieve stable, low, late diastolic thresholds, and a variety of left atrial positions were used to measure the interatrial conduction time. This procedure probably caused the distances between recording electrodes to be relatively short and variable from patient to patient. The methodology may have prevented us from detecting the expected difference in interatrial and intraatrial conduction of nonpremature beats between the 2 groups.

It is possible that the prolongation of conduction times may have been caused by a shift in atrial conduction pathway of early premature beats. However, the continuous increase in conduction time during the relative refractory period, the constancy of the atrial activation sequence, and the fact that both inter- and intraatrial conduction increased, and not one or the other, suggests that conduction slowing rather than a shift in pathway was responsible for the observed changes. Moreover, since atrial conduction for distances of up to several centimeters is believed to be radial from the point of stimulation, a shift in conduction pathway would be unlikely.[23–25] Neither the influence of the autonomic nervous system on atrial conduction nor the theoretical difficulty of measuring conduction independently of excitability, as outlined elsewhere,[22,26–28] can explain the increase in conduction time of early premature responses which we observed in the patients with diseased atria.

It is not surprising that some markers of atrial excitability were similar in patients with normal and prolonged P-wave durations. These markers included the duration of the atrial refractory periods and the shape of the atrial strength-interval curve (that is, the presence, magnitude, or duration of a decrease in threshold before the effective refractory period). Atrial refractory period varies with paced cycle length and electrode position and is probably not useful as a method of separating normal from disease atria.[29–31] Our observation, that a decrease in threshold could be introduced at short $S_1–S_2$ intervals by reversing the polarity of the pacing stimulus, suggests that anodal pacing is the primary cause of the enhanced excitability seen in our patients.

The finding of a large difference in the diastolic threshold of Group I and II patients was unexpected. The possible existence of differences in the geometry or size of the right atrium of Group II patients, causing poor electrode contact with the atrial wall, does not fully account for this finding. Catheter positions were stable in both groups. Nor can this difference in thresholds be explained by the bipolar configuration of the pacing electrodes. Both anodal and cathodal current can stimulate the heart, depending on which electrode is in better contact and which phase of repolarization the excitable tissue is undergoing.[22] The excitability curves of the 1 patient in Group I and 3 patients in Group II demonstrated a decrease in threshold at early S_1–S_2 intervals as seen in anodal strength interval curves. Since anodal stimulation may have a higher threshold in late diastole, we analyzed our results excluding these 4 patients and still found a significant difference in late diastolic threshold between the 2 groups ($p < 0.005$).

We believe this difference in diastolic threshold is evidence of the importance of excitability in determining conduction velocity in human atrial tissue. Single-fiber studies and experiments with intact animals have demonstrated a close relation between excitability and conduction velocity. Factors that increase the current required to induce a propagated response tend to slow conduction of the response, and some investigators consider excitability a major determinant of conduction velocity.[32] Our studies of human atria corroborate the association of depressed conduction with depressed excitability.

We expected patients with a history of atrial fibrillation to show a greater increase in atrial conduction time than patients without such a history. That this did not occur may be explained by several factors; of these, study design and patient selection may be most important. Further prospective studies specifically designed to test the correlation between slowed conduction of early atrial premature responses and atrial fibrillation are needed.

Conclusions: We found elevated late diastolic threshold and abnormal conduction of early premature atrial beats in a group of patients with a prolonged P-wave duration and a history of atrial arrhythmias. Our study suggests that repetitive atrial firing and sinus echo beats may occur in this group of patients because of slow conduction of early premature beats. The slowed conduction, coupled with the shortened refractoriness known to characterize early premature beats,[33] provides an ideal electrophysiologic substrate for reentry and development of these atrial tachyarrhythmias.

Acknowledgment: We are grateful to Ingrid Amara for help with the statistics, to Lynn Evans for assisting in the measurement of the P-wave durations, and to Donna Goans for secretarial assistance.

Termination of Ventricular Tachycardia

Evaluation of a New Pacing Method

MARTIN J. GARDNER, MD, HARVEY L. WAXMAN, MD, ALFRED E. BUXTON, MD, MICHAEL E. CAIN, MD, and MARK E. JOSEPHSON, MD

Ventricular extrastimuli or rapid ventricular pacing used to terminate ventricular tachycardia (VT) may be ineffective or may accelerate VT. Therefore, a new method to facilitate termination of VT and decrease the incidence of acceleration was evaluated. The new method utilized rapid ventricular pacing at cycle lengths 10 to 100 ms shorter than VT cycle length with the introduction of 1 or 2 ventricular extrastimuli. The efficacy of this combination method in terminating VT was assessed in 25 patients in whom ventricular extrastimuli and rapid ventricular pacing at cycle lengths and coupling intervals comparable with those used in the new method were unsuccessful. This combination method successfully terminated VT in 21 of 25 patients with cycle lengths of 230 to 400 ms. VT was terminated in 6 of 8 patients receiving drugs in whom VT could not be terminated by 1 to 2 ventricular extrastimuli or rapid ventricular pacing; in 6 of 8 patients unresponsive to ventricular extrastimuli and in whom rapid ventricular pacing produced acceleration of VT; and in 9 of 9 patients in whom antiarrhythmic agents made VT unresponsive to ventricular extrastimuli or rapid ventricular pacing. A combination of rapid pacing and extrastimuli can terminate VT unresponsive to ventricular extrastimuli or rapid ventricular pacing alone and may avoid acceleration of VT using rapid ventricular pacing at very short cycle lengths for termination.

Programmed stimulation of the heart has permitted investigation of patients with recurrent ventricular tachyarrhythmias through induction of their arrhythmias, enabling assessment of specific drug therapy.[1–8] Termination of VT in the electrophysiology laboratory by pacing techniques has allowed these studies to be done with relative safety and minimal discomfort to the patient. Furthermore, termination procedures may be used as a guide for potential pacemaker therapy in patients with drug-resistant arrhythmias.[3,9–13] Successful termination of VT using implantable pacemakers has been described previously. These techniques, however, are not without risk.

Introduction of 1 or more premature extrastimuli during VT or rapid overdrive pacing may fail to terminate VT and, in some cases, results in acceleration of VT or degeneration to ventricular fibrillation, or both, requiring cardioversion or defibrillation.[3,4,9,10] Such occurrences increase the risk and discomfort to the patient, and limit the use of pacing as a therapeutic technique.

The reported incidence of acceleration of VT or degeneration to ventricular fibrillation varies from 7 to 50%; the latter figure is associated with very rapid overdrive pacing rates.[3,4,9,10] In an effort to improve our ability to terminate VT successfully and to reduce the incidence of acceleration, a new method of programmed stimulation combining overdrive pacing with premature stimulation was evaluated.

Methods

Patients: The study population included 25 patients who were undergoing electrophysiologic studies for the evaluation and management of recurrent sustained VT or who were

survivors of cardiac arrest. There were 17 men and 8 women, aged 34 to 74 years. Twenty-one of the 25 had ischemic heart disease, all of whom had previous myocardial infarction and 16 of whom had left ventricular aneurysms. The site of infarction was anterior in 13 patients and inferior in 7. One patient had both anterior and inferior infarctions. The remaining patients had arrhythmogenic right ventricular dysplasia, idiopathic congestive cardiomyopathy, and mitral valve prolapse. Fourteen of the patients were taking antiarrhythmic agents at the time of the study.

In all patients, VT was inducible by programmed stimulation using previously reported methods.[1,8,9] In each of these patients, the tachycardia was stable enough so that the ability of single or multiple extrastimuli and rapid pacing as methods of terminating the tachycardia could be evaluated. The termination protocol was identical to our standard protocol.[1,8,9] A single premature stimulus was coupled to the right ventricular electrogram at progressively decreasing intervals until refractoriness was reached. If the tachycardia persisted, a second and occasionally a third extrastimulus was introduced in a similar fashion. If these methods failed to terminate tachycardia, asynchronous bursts of stimuli were given to ensure 6 to 10 captures. These bursts were delivered initially at cycle lengths 10 ms less than that of the tachycardia and progressively decreased by 10 to 25 ms decrements to 225 to 250 ms, or until acceleration of tachycardia occurred. In all instances, VT either could not be terminated or was accelerated by single, double, or triple extrastimuli or by rapid pacing. All stimulation was performed with a specially designed programmable stimulator (Bloom Associates, Narberth, Pennsylvania) using rectangular pulses 1 ms in duration at twice diastolic threshold.

The patients were divided into 3 groups based on response to stimulation during VT and the effects of antiarrhythmic agents. Although somewhat arbitrary, the separation of patients allows consideration of all the specific situations in which the combination method might be useful. There was no difference in mean VT cycle length among the groups. The first group included 8 patients (Cases 1 to 8, Table I) in whom premature stimuli and overdrive pacing were ineffective in terminating VT. A second group of 8 patients (Cases 9 to 16) included those in whom overdrive pacing resulted in acceleration of VT or degeneration of this rhythm to ventricular fibrillation. Five of these patients were taking antiarrhythmic agents at the time of the study. In all instances, the response of rapid pacing with the antiarrhythmic agents was identical to that seen before administration of the antiarrhythmic agents. A third well-defined group of patients included 9 patients (Cases 17 to 25) in whom premature stimuli or overdrive pacing had successfully terminated VT in the baseline state (that is, with no antiarrhythmic drugs present) but were ineffective in terminating VT after therapy with the antiarrhythmic agents listed in Table I.

Combination method protocol: After attempts to terminate tachycardia using the standard methods listed (Table I), a combination method, consisting of the introduction of 1 or more ventricular premature stimuli after 8 to 10 beats of overdrive pacing, was employed. Overdrive pacing was given as asynchronous bursts 10 to 100 ms faster than the VT cycle length and was identical to overdrive-paced cycle lengths that were ineffective in terminating tachycardia. The premature stimuli were delivered at coupling intervals previously shown incapable of terminating tachycardia by themselves. No systematic analysis of later or earlier stimuli was performed. An example of the combination method is shown in Figure 1. VT with a left bundle branch block pattern and a cycle length of 400 ms is not terminated by a single premature stimulus or rapid pacing. The combination of pacing and premature stimulus, at the same cycle length and coupling interval noted to be individually ineffective abruptly terminates tachycardia.

ANT = anterior wall; AR = aortic regurgitation; CA-VF = cardiac arrest-ventricular fibrillation; CM = cardiomyopathy; IHD = ischemic heart disease; INF = inferior wall; MVP = mitral valve prolapse; RVD = right ventricular dysplasia; RVT = recurrent ventricular tachycardia.

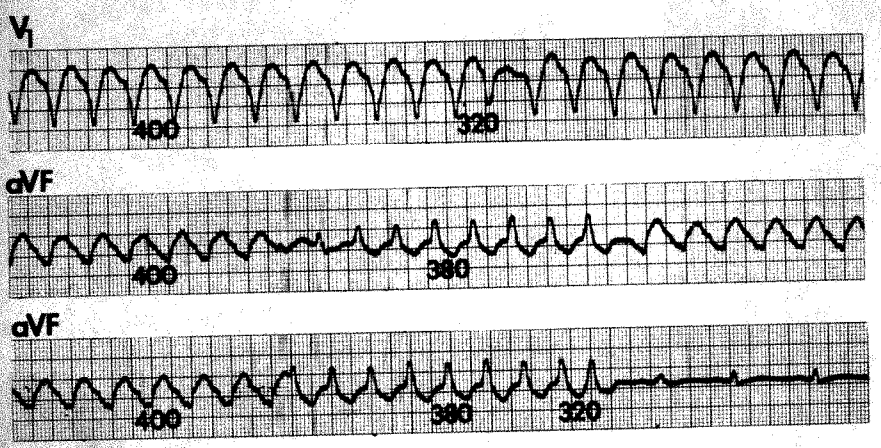

FIGURE 1. Termination of VT by the combination method in Patient 4. VT at a cycle length of 400 ms is present in all 3 rhythm strips. In the **top panel,** a single ventricular extrastimulus at a coupling interval of 320 ms fails to terminate the tachycardia. In the **middle panel,** bursts of ventricular pacing at a cycle length of 380 ms fail to interrupt the tachycardia. In the **bottom panel,** pacing at 380 ms and the addition of a single premature stimulus at a coupling interval of 320 ms abruptly terminate the tachycardia.

Two or 3 electrocardiographic leads I, II or aVF, and V_6 were simultaneously recorded with intracardiac electrograms from the right ventricular apex. Other intracardiac electrograms, including those from the left ventricle (6 patients), were also recorded in many but not all patients.

All data were displayed on a physiologic recorder (Electronics for Medicine VR16) and recorded on an ink jet system (Elema Mingograf) at paper speeds of 100 to 250 mm/s. Data were stored on magnetic tape (Honeywell 5600C) for subsequent retrieval.

Results

The overall results of using the combination method are summarized in Table II. This new method successfully terminated VT in 21 of the 25 study patients (84%), in each of whom rapid pacing and premature stimuli individually at similar cycle lengths and coupling intervals had failed to interrupt tachycardia. The paced cycle length and coupling interval of the premature stimulus (or stimuli) used in combination were, in all but 2 patients (Cases 3 and 8), the same paced cycle length and coupling interval(s) which proved ineffective in terminating VT when delivered individually. In these 2 patients, the ability to attain the same coupling interval used during the combination method was limited by ventricular refractoriness during tachycardia. Thus, during tachycardia the refractory period determined by a single extrastimulus during VT was longer than that achieved during the combination method. Of note is the fact that in both patients the introduction of 2 extrastimuli during tachycardia failed to terminate it despite

CL = cycle length; Methods 1, 2, 3 = number of extrastimuli; RVP = rapid ventricular pacing.

the fact that the shortest coupling interval of the second extrastimulus was less than that used in the successful combination method. No patient in the study group manifested acceleration of tachycardia with the combination method.

None of the first group of 8 patients were taking antiarrhythmic drugs at the time of the study. In 6 of these 8 patients, the induced VT was terminated with the combination method when premature stimuli alone and overdrive pacing alone at comparable cycle lengths were unsuccessful (Fig. 1). Two patients (Cases 3 and 5) were unresponsive to this method as well—1 required cardioversion and in the other VT was terminated by an additional burst of rapid pacing at an extremely short cycle length (180 ms).

In 8 patients (Cases 9 to 16), premature stimuli delivered during VT failed to terminate the arrhythmia, and overdrive pacing at cycle lengths of 225 to 280 ms resulted in acceleration of VT in each case. The combination method was successful in terminating VT in 6 of these 8 patients. An example is shown in Figure 2. Overdrive pacing at a cycle length of 300 ms was ineffective, and pacing at a cycle length of 250 ms resulted in acceleration of VT; this was accompanied by loss of consciousness and cardioversion was required for termination. The same VT, however, could be reproducibly terminated by the combination method using overdrive pacing at a cycle length of 300 ms plus a single premature stimulus. Two patients (Cases 15 and 16) in this subgroup did not respond to the combination method and required cardioversion or a more rapid burst of pacing (cycle length 220 ms) than that previously causing acceleration.

In 9 patients (Cases 17 to 25) VT was successfully terminated with 1 or 2 premature stimuli or overdrive pacing before administration of antiarrhythmic drugs.

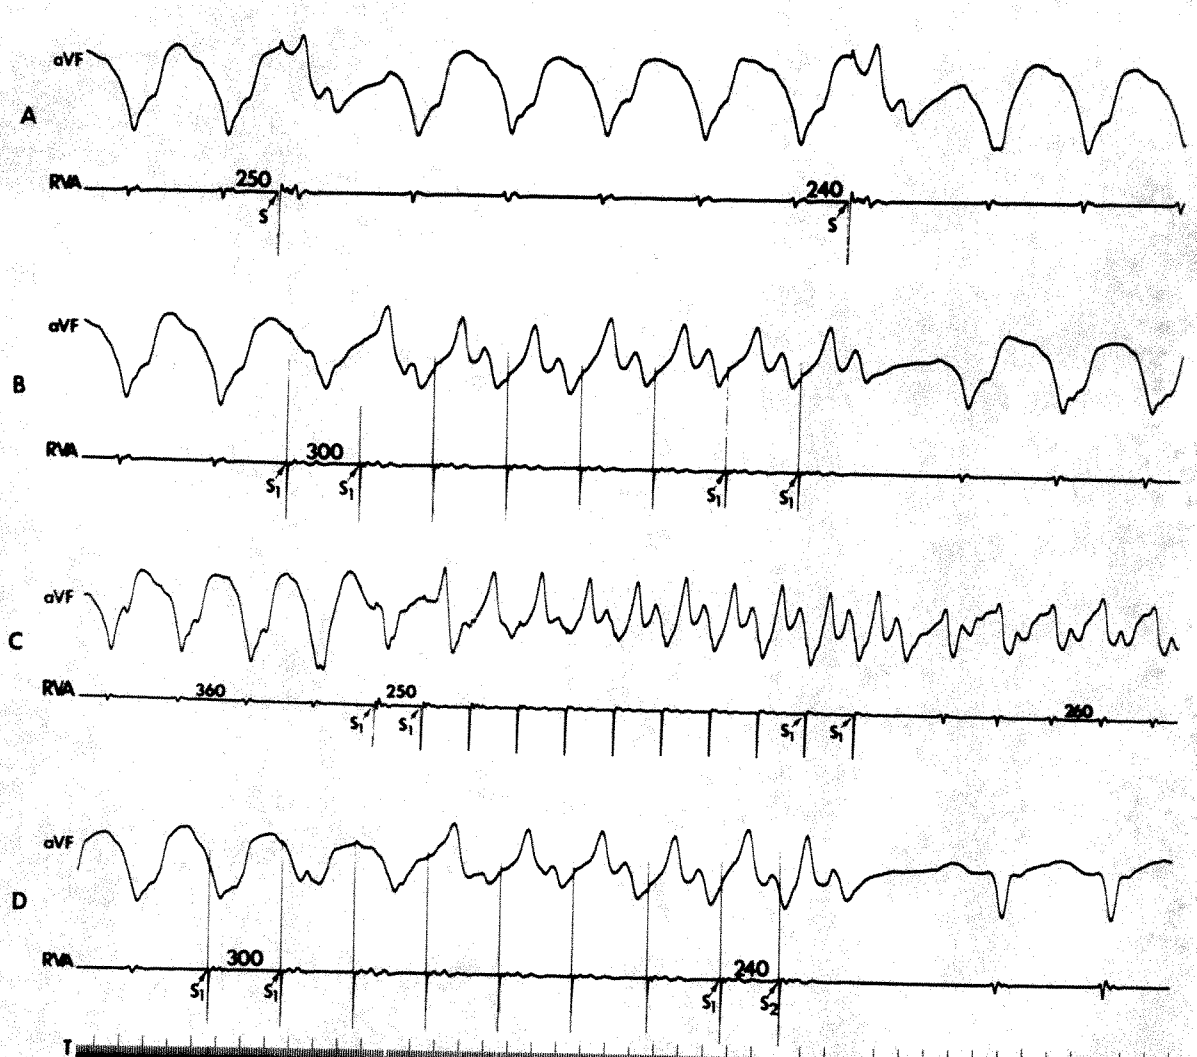

FIGURE 2. Combination method in Patient 14. Each panel shows recordings of lead aVF and the right ventricular apex (RVA). In **panel A,** a single premature stimulus (S) fails to terminate VT. In **panel B,** overdrive ventricular pacing at a paced cycle length of 300 ms (S_1—S_1) is also unsuccessful. In **panel C,** overdrive ventricular pacing at a paced cycle length of 250 ms results in acceleration of VT from a cycle length of 360 ms to 260 ms. A subsequent episode of VT is shown in **panel D.** In this case, a combination of overdrive pacing at a paced cycle length of 300 ms plus a single premature stimulus succeeds in restoring sinus rhythm. T = time line.

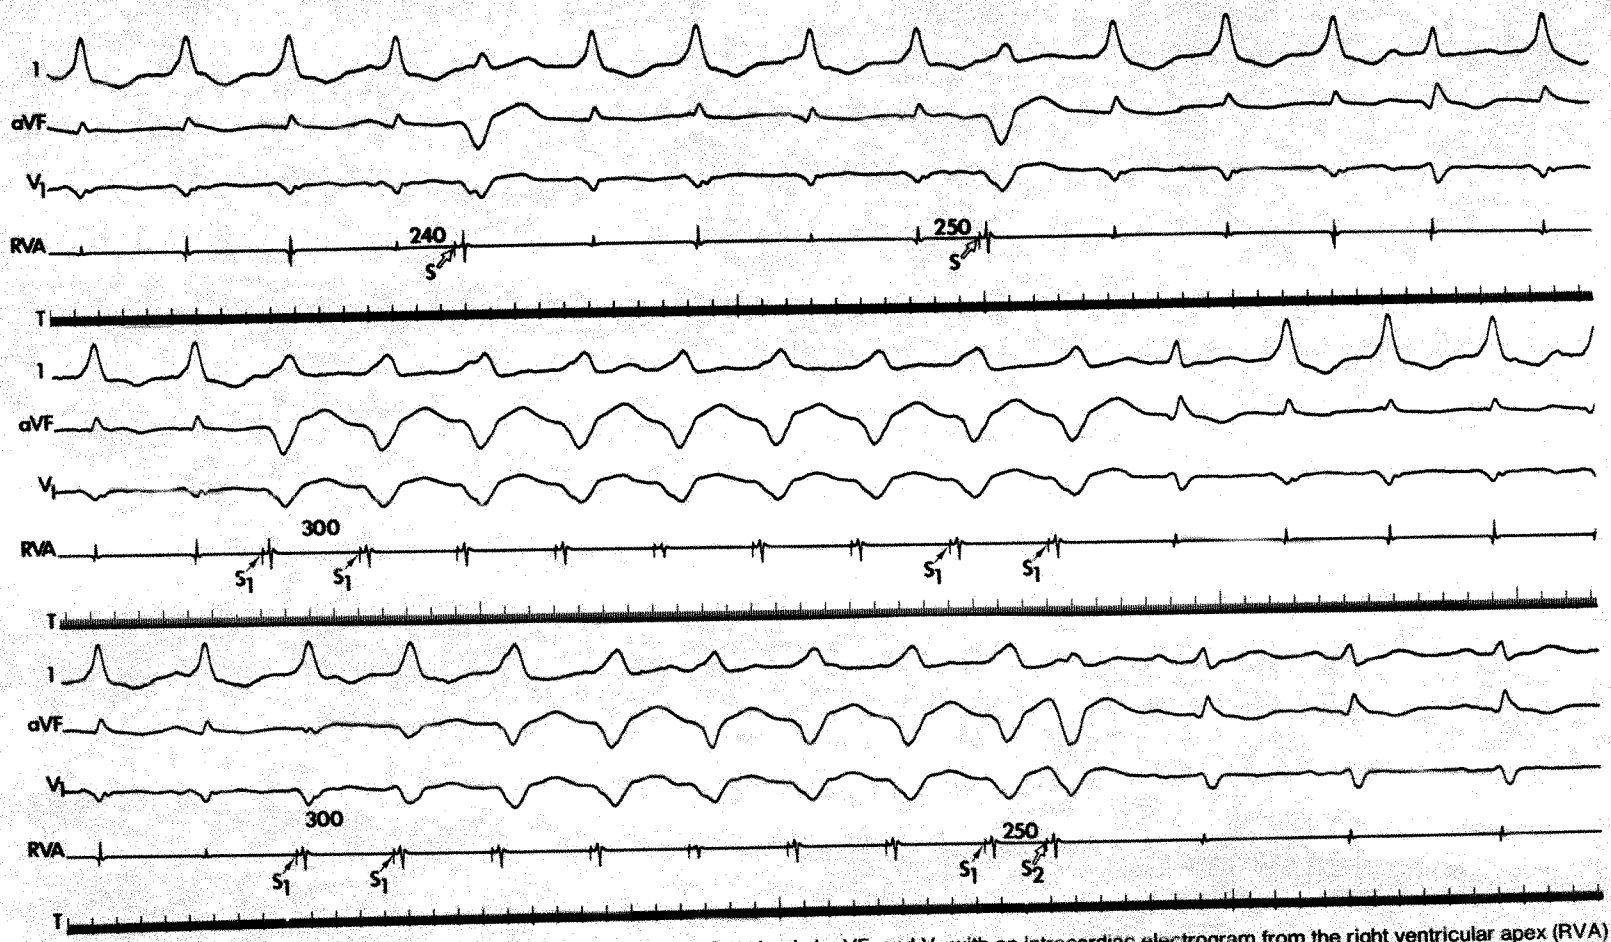

FIGURE 3. Example of combination method protocol. Each panel has surface leads I, aVF, and V_1 with an intracardiac electrogram from the right ventricular apex (RVA) and time lines (T). A left bundle branch block morphology VT is present. In the **top panel,** single premature stimuli (S) are introduced at the RVA at coupling intervals of 240 and 250 ms. Note that capture of the ventricles is accomplished with a change in the QRS morphology, but VT continues. Also evident in this panel is a sinus capture beat. In the **middle panel,** the VT is captured by overdrive ventricular pacing (S_1—S_1) at a paced cycle length of 300 ms, but the VT continues when the pacing is stopped. In the **bottom panel,** overdrive pacing at the same paced cycle length (300 ms) is followed by a premature stimulus (S_2) at a coupling interval previously shown ineffective. With this combination, however, sinus rhythm is restored.

However, after the administration of an antiarrhythmic agent (which failed to prevent induction of VT) these methods were no longer successful, despite slowing of the tachycardia. Thus, these patients represented a group in whom antiarrhythmic agents made termination of tachycardia more difficult. Tachycardia became incessant in 4 patients and 4 others exhibited sinus captures suggesting protection of the circuit. In all 9 patients, the combination method successfully terminated the induced VT. An example is shown in Figure 3. This patient had a left bundle branch block morphology VT with a cycle length of 400 ms. A sinus capture beat is present in the top panel A, indicating capture of a large part of the ventricular myocardium without interruption of VT. Single premature stimulus (top panel) and overdrive ventricular pacing (middle panel) could not terminate the VT. A combination of a single premature beat, plus overdrive pacing at the same coupling interval and paced cycle length previously shown to be ineffective, resulted in conversion of VT to sinus rhythm (bottom panel).

Discussion

The ability to initiate and terminate VT using programmed stimulation has been extremely useful in helping establish therapeutic regimens for patients with this arrhythmia.[1–10] The ability to reproducibly terminate tachycardia allows multiple studies to proceed without the need for multiple cardioversions. In addition, the efficacy of pacemaker therapy can be tested by assessing the modes of stimulation required for termination.

One of the major concerns, however, is that VT can be accelerated by pacing techniques, resulting in a more rapid tachycardia with hemodynamic embarrassment, degeneration to ventricular fibrillation, or both. Acceleration of VT by pacing has been reported to occur in 7 to 50% of episodes of VT and in up to 50% of patients with this arrhythmia.[3,4,9,10] Acceleration is most likely to occur with very vigorous pacing techniques such as multiple extrastimuli or bursts of rapid pacing.[3,4,9] As reported by Fisher et al[3] and Mason and Winkle,[4] as well as in our own experience, acceleration is most likely to occur when bursts of pacing are delivered at cycle lengths <250 ms to convert tachycardias which are rapid, with cycle lengths <300 ms. The incidence of acceleration with single or double extrastimuli is less.[3,4] Unfortunately, however, rapid tachycardias (that is, with a cycle length <300 ms) frequently require rapid bursts of pacing for termination.

Several factors determine the ability to terminate reentrant arrhythmias: the relation between the site of stimulation and site of the tachycardia circuit, the cycle length of the tachycardia, and the electrophysiologic characteristics (such as refractoriness and conduction) of local and intervening tissues. These factors determine when the tachycardia can be terminated by precisely timed stimuli.

As the ventricles are depolarized from the site of the VT circuit, the activation wave front spreads outward from this circuit to reach the site of stimulation. This activation wave front takes a finite period of time to reach the site of stimulation. It is followed by a wave of refractoriness that limits the prematurity with which a stimulus can be delivered at the site of stimulation. If the tachycardia cycle length is short or conduction of the stimulation impulse is slow, or both, a propagated stimulus often meets the oncoming wave front of activation, colliding with it and therefore failing to reach and penetrate the tachycardia circuit. Thus, the VT circuit is relatively protected by its own activation wave front and subsequent time of refractoriness. Overdrive pacing or the introduction of multiple extrastimuli reverses the activation wave front over the several delivered stimuli until the wave front of activation is reversed from the point of stimulation toward the tachycardia circuit. Even if the wave front of refractoriness is reversed by rapid pacing, the tachycardia may only be reset or, on occasion, may be stopped and then inadvertently started again.

While more rapid bursts of pacing may, in fact, terminate such tachycardias, under these circumstances, acceleration of the arrhythmia is also more likely.[3,4,10] The combination method of stimulation described herein represents an alternative to more rapid bursts of pacing. The ability to reverse refractoriness by rapid pacing allows a premature stimulus to be introduced earlier, so as to arrive at a critical time to produce bidirectional block within the tachycardia circuit and terminate the arrhythmia (Fig. 4). This method uses pacing at cycle lengths only slightly shorter than the tachycardia, which are less likely to induce acceleration. The overdrive pacing shortens local refractoriness, changes the wave front of activation and pattern of subsequent refractoriness, and allows a premature depolarization to reach the reentrant circuit at a critically timed interval to collide with the circulating impulse, thereby terminating the tachycardia. This system avoids the use of very rapid bursts of pacing which are likely to accelerate the tachycardia. The present study did not permit evaluation of whether shortening local refractoriness or changing the direction of the wave front of activation is the more important factor in the ability to terminate arrhythmias using this method. However, in only 2 patients could shortening of local refractory periods be implicated as related to the success of the new method.

Therapeutic uses: Acceleration of VT has been a problem with standard burst pacing or the use of multiple extrastimuli to terminate tachycardia during either a chronic drug study or an attempt to evaluate the most effective pacing method. Most patients who have a permanent pacemaker and are considered for the termination of recurrent tachycardia are taking such antiarrhythmic agents. The use of this newly described stimulation method assumes great importance in long-term drug studies since pharmacologic agents, particularly the membrane active types, are associated with slowing of the tachycardia.[2,8,9] Sinus captures suggesting protection of the circuit are also encountered

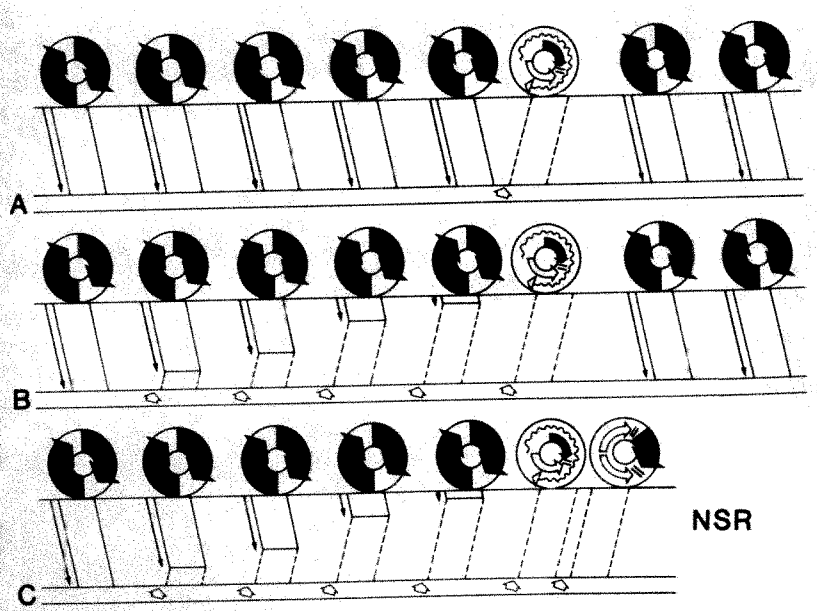

FIGURE 4. Mechanism of combination method. In each panel the assumed reentrant circuit is schematically shown as the circle. The **long, thin arrow** and **adjacent enclosed area** represent the activation wave front and obligatory accompanying refractory period. In **panel A,** a very early ventricular extrastimulus reaches the circuit but can only produce block in one direction, and therefore resets the circuit. In **panel B,** rapid pacing is shown to reverse the wave front of activation and refractoriness but still is only able to reset the tachycardia. In **panel C,** with the combination method, the premature stimulus reaches the circuit early enough to produce bidirectional block and terminate tachycardia. While the extrastimulus was delivered at the same coupling interval as in **panel A,** it reaches the tachycardia circuit earlier by the amount of time it took for the impulse to travel from the tachycardia circuit to the site of stimulation.

more frequently under these circumstances. In our experience, type I agents can make termination of VT more difficult or cause the tachycardia to become incessant, or both, in almost 25% of cases (unpublished observations). Although we cannot predict which patients will have this reaction; however, one obvious clue to such a circumstance is the presence of sinus captures (Fig. 3). These patients may be at relatively high risk for acceleration or degeneration to ventricular fibrillation when rapid pacing or multiple extrastimuli are introduced, due to the markedly prolonged conduction and refractoriness of intervening tissue produced by these drugs. These changes can lead to the development of local areas of block and chaotic conduction patterns between the site of stimulation and the reentrant circuit—circumstances which increase the tendency to fibrillation. Thus, the combination method of stimulation should be considered in patients who require type I drugs.

The development of more sophisticated pacemakers for the management of VT should probably incorporate the ability to introduce premature stimuli after a given number of drive stimuli during tachycardia. The laboratory demonstration of the efficacy of this type of pacemaker is important when pacing therapy is a consideration in the management of these arrhythmias.

Limitations: The present study did not address several aspects of the pacing protocol that might have bearing on the efficacy and safety of the new method of termination. These include the coupling interval of the first beat of the train of stimuli to the tachycardia, the rate of overdrive pacing, the duration of overdrive pacing, and the coupling interval of premature stimuli.

The coupling interval of the onset of the train of stimuli was variable in the present study, since the burst was delivered in an asynchronous mode. For example, a train of stimuli at a cycle length of 300 ms could have begun with the first stimulus of that train having a variable coupling interval to the tachycardia of 200 to 300 ms. The variable coupling interval may be important with regard to the ability to terminate or accelerate tachycardia.

The rate of duration of rapid pacing were not studied either. The combination method of stimulation might have been more effective if pacing had been continued for a longer period to ensure complete reversal of the activation wave front to the tachycardia, in order to more rapidly facilitate penetration of the tachycardia. On the other hand, more rapid pacing rates will probably reverse the activation wave front more quickly; thus, a shorter burst would be necessary. However, it is known that the slower the overdrive, that is, with overdrive <120% of the VT cycle length, the lower the incidence of acceleration.[10] This slower rate may require a longer duration of pacing and hence a greater number of captures to ensure a total change in the direction of the wave front and recovery of excitability, which allows the ventricular premature depolarization to reach and penetrate the circuit to terminate tachycardia. More rapid rates, which may be more prone to accelerate tachycardia, require a shorter duration of pacing in order to capture the ventricles and change the wave front of activation. The exact paced rate and duration, as well as coupling intervals, which are both safest (with respect to acceleration) and most efficient should be determined for each patient.

Conclusion: Thus, while this combination method of termination of tachycardia appears to be a promising new mode of stimulation which can terminate tachycardia safely and efficiently, further studies are needed to ascertain the role of varying the coupling interval of the first stimulus of the train of stimuli, as well as the rate and duration of the train, and the coupling intervals of the premature stimuli. This will require the use of sophisticated stimulators, and indicates the complex requirements of antitachycardia pacing systems which need to be developed in the future.

Termination of Ventricular Tachycardia: Role of Tachycardia Cycle Length

DENIS ROY, MD,* HARVEY L. WAXMAN, MD, ALFRED E. BUXTON, MD,†
FRANCIS E. MARCHLINSKI, MD,‡ MICHAEL E. CAIN, MD,‡
MARTIN J. GARDNER, MD,§ and MARK E. JOSEPHSON, MD‖

The mode of termination of ventricular tachycardia (VT) and its relation to tachycardia cycle length was evaluated in 139 patients. Tachycardia was terminated by programmed stimulation in 110 patients (79%) and cardioversion was required in 29 patients (21%). Single, double, and triple ventricular extrastimuli terminated the tachycardia in 23 of 85 (27%), 39 of 62 (63%), and 7 of 16 patients (44%), respectively. In all patients requiring 1 extrastimulus, in 35 patients (90%) requiring 2 extrastimuli, and in 6 patients (86%) requiring 3 extrastimuli, the tachycardia cycle length exceeded 300 ms. Rapid ventricular pacing terminated tachycardia in 41 of 54 patients (76%). In 21 (51%) of these patients the tachycardia cycle length exceeded 300 ms. However, rapid ventricular pacing caused acceleration of the arrhythmia in 19 patients (35%). The ability of procainamide to modify the termination of VT was studied in 23 patients. In 7 of these patients (30%) procainamide increased the tachycardia cycle length by 49 ± 42 ms ($p < 0.01$) and did not modify the mode of termination. In 6 patients (26%) procainamide increased cycle length by 142 ± 108 ms ($p < 0.01$), but termination was more difficult. In 10 patients (44%) procainamide increased the cycle length by 138 ± 110 ms ($p < 0.001$) and termination was easier. We conclude that termination of VT by timed extrastimuli requires a tachycardia cycle length longer than 300 ms. Rapid pacing or cardioversion is usually required when the cycle length is less than 300 ms. Although procainamide slows tachycardia, it can unpredictably make termination more difficult in 1 of 4 patients.

Programmed ventricular stimulation is increasingly used to evaluate the mechanisms and therapy of recurrent VT. Previous studies have shown that in the majority of patients in whom VT can be initiated by programmed ventricular stimulation, the arrhythmia can also be terminated by appropriately timed extrastimuli or by rapid ventricular pacing.[1–5] The pacing techniques employed during electrophysiologic testing may serve as a guide for chronic pacemaker therapy of drug-resistant ventricular arrhythmias.[6] It has been suggested that the mode of termination of VT is related to tachycardia cycle length. However, the relation between the specific mode of termination and the tachycardia cycle length has never been systematically evaluated in a large group of patients. The aims of this study are (1) to analyze the relation of mode of termination of VT to tachycardia cycle length, and (2) to assess the influence of procainamide on tachycardia cycle length and mode of tachycardia termination.

Methods

Patients: The study population consisted of 139 patients with recurrent VT or cardiac arrest in whom sustained VT was induced by programmed ventricular stimulation. There were 104 men and 35 women ranging in age from 8 to 74 years. Coronary artery disease was present in 101 patients, miscellaneous cardiac abnormalities (cardiomyopathy, repair of tetralogy of Fallot, hypertensive cardiovascular disease, and mitral valve prolapse) in 22, and no documented clinical organic heart disease in the remaining 16.

Electrophysiologic procedures: After informed consent was obtained, the patients underwent electrophysiologic

testing in the nonsedated postabsorptive state. The administration of all antiarrhythmic agents was discontinued at least 48 hours before the procedure. Three or more electrode catheters were inserted percutaneously or by venous cutdown and positioned in the heart under fluoroscopic guidance. These usually included quadripolar catheters in the right atrium and right ventricle and a tripolar catheter at the atrioventricular junction for recording His bundle electrograms. Electrical stimulation was performed with a specially designed digital stimulator and isolated constant current source (Bloom Associates, Narberth, Pennsylvania). The stimuli were rectangular pulses 1 ms in duration at twice diastolic threshold. Intracardiac recordings were filtered at 30 to 500 Hz and simultaneously recorded with 3 electrocardiographic leads. Stimulation techniques for initiating VT included the introduction of single, double, triple, or quadruple ventricular extrastimuli from the right ventricle during sinus rhythm or during ventricular pacing at 2 or 3 different basic cycle lengths. The stimulation protocol during VT included the introduction of 1 ventricular extrastimulus from the right ventricle scanning diastole until ventricular refractoriness was reached. If a single stimulus did not terminate tachycardia, 2 and sometimes 3 extrastimuli were introduced; the coupling intervals of the extrastimuli were varied until refractoriness was reached. If timed extrastimuli failed to terminate the tachycardia or if hemodynamic embarassment was marked, bursts of rapid ventricular pacing for 5 to 60 seconds starting at a cycle length 10 ms shorter than the tachycardia cycle length were employed. The protocol was altered to begin with more vigorous pacing techniques if tachycardia was hemodynamically unstable.

The effect of procainamide on tachycardia cycle length and termination was evaluated in 23 patients in whom tachycardia could be induced after the intravenous administration of procainamide 500 to 2,000 mg at 50 mg/min.

Results

Termination of VT: The ability of programmed ventricular stimulation to terminate VT could be studied in 123 patients. In 16 patients, programmed ventricular stimulation could not be evaluated because the tachycardia caused hemodynamic deterioration and immediate cardioversion was required. VT could be terminated by some form of programmed stimulation in 110 patients (79%). In 13 patients rapid ventricular pacing caused acceleration of the tachycardia and cardioversion was ultimately employed to terminate the arrhythmia.

Effect of programmed ventricular stimulation during VT (Table I): A single ventricular premature stimulus terminated VT in 23 of the 85 patients (27%) in whom this technique was tested. Double and triple ventricular extrastimuli terminated the tachycardia in 39 of 62 patients (63%) and 7 of 16 patients (44%), respectively. Rapid ventricular pacing terminated the tachycardia in 41 of the 54 patients (76%) in whom it was attempted.

Acceleration of VT (shortening of the tachycardia cycle length by 30 ms or more) occurred in 24 (20%) of the 123 patients who underwent ventricular stimulation during VT. Single, double, and triple extrastimuli caused acceleration of VT in a total of 5 patients, none of whom needed cardioversion. Rapid ventricular pacing produced acceleration in 19 of 54 patients (35%), 13 of whom required cardioversion because of hemodynamic deterioration or degeneration to ventricular fibrillation. The mean tachycardia cycle length was 325 ms (range 315 to 330) in the 5 patients in whom single (1 patient), double (2 patients), and triple extrastimuli (2 patients) produced acceleration of the tachycardia. The mean tachycardia cycle length was 282 ms (range 240 to 400) in the 19 patients whose tachycardia was accelerated by rapid ventricular pacing.

TABLE I Effects of Programmed Ventricular Stimulation (PVS) During VT (123 Patients)

Mode of PVS	Patients (n)	Termination		Acceleration	
		n	%	n	%
1 VES	85	23	27	1	1.2
2 VES	62	39	63	2	3.2
3 VES	16	7	44	2	13
RVP	54	41	76	19	35

RVP = rapid ventricular pacing; VES = ventricular extrastimuli.

Relation between mode of termination of VT and tachycardia cycle length (Table II): The tachycardia cycle length was longer than 300 ms in all 23 patients in whom a single ventricular extrastimulus terminated the arrhythmia, and in 16 of these patients the cycle length was longer than 400 ms. The tachycardia cycle length exceeded 300 ms in 35 of the 39 patients (90%) in whom tachycardia was terminated by 2 ventricular extrastimuli and in 6 of 7 patients (86%) in whom 3 ventricular extrastimuli terminated tachycardia. In 45 of the 50 patients who had a tachycardia cycle length <300 ms, rapid ventricular pacing (20 patients) or cardioversion (25 patients) was required to terminate tachycardia.

Effect of procainamide on mode of termination of VT (Table III): The effect of procainamide on the ability to terminate VT was studied in 23 patients in whom the drug failed to prevent initiation of VT. The mean tachycardia cycle length was 280 ms (range 180 to 390) before administration of procainamide and was 392 ms (range 200 to 670) after procainamide with a mean increase of 112 ± 99 ms (range 0 to 370) ($p < 0.00001$). The average dose of procainamide was 1,595 mg (500 to 2,000), resulting in a mean plasma level of 11.4 μg/ml (range 4.3 to 27.2). In 7 patients (30%) the mode of termination before and after procainamide was

TABLE II Relation of Mode of Termination of VT With Cycle Length (139 Patients)

Mode of Termination	VT Cycle Length (ms)				
	400–500	350–400	300–350	<300	VT (n)
1 VES	16	5	2	...	23
2 VES	12	15	8	4	39
3 VES	...	3	3	1	7
RVP	1	5	15	20	41
Cardioversion	...	2	2	25	29
VT (n)	29	30	30	50	139

Abbreviations as in Table I.

TABLE III Effect of Procainamide on Mode of Termination of VT (23 Patients)

Effect	Patients n	Patients %	Mean Dose (mg)	Mean Plasma Level (μg/ml)	Mean VT Cycle Increase (ms)
Unchanged	7	30	1,460	7.5	49 ± 42 (p <0.01)
Harder	6	26	1,500	12.9	142 ± 108 (p <0.01)
Easier	10	44	1,750	13.7	138 ± 110 (p <0.001)

similar. The mean increase in the tachycardia cycle length in these patients was 49 ± 42 ms (p <0.01). In 6 patients (26%) in whom procainamide produced a mean increase of 142 ± 108 ms (p <0.01) in the tachycardia cycle length, termination was more difficult. In 2 of these patients a single premature stimulus terminated the tachycardia before procainamide, but 2 extrastimuli were required after procainamide (Fig. 1). In 3 patients rapid ventricular pacing terminated the arrhythmia before procainamide but was no longer successful after procainamide. All 3 patients required cardioversion to sinus rhythm. In the remaining patient the cycle length increased from 275 to 600 ms after procainamide, but the arrhythmia became incessant and could not be terminated by pacing techniques or cardioversion. In 10 patients (44%) in whom procainamide increased the cycle length by 138 ± 110 ms (p <0.001) tachycardia termination was facilitated. Tachycardia terminated spontaneously in 4 of these patients. In 4 others tachycardia was terminated by rapid pacing at cycle lengths 40 to 175 ms longer than before procainamide. In 1 patient procainamide made it possible to terminate tachycardia with 2 extrastimuli instead of rapid pacing. In the last patient rapid pacing caused degeneration to ventricular fibrillation in the baseline state, whereas after procainamide rapid pacing at a longer cycle length than that during control terminated tachycardia.

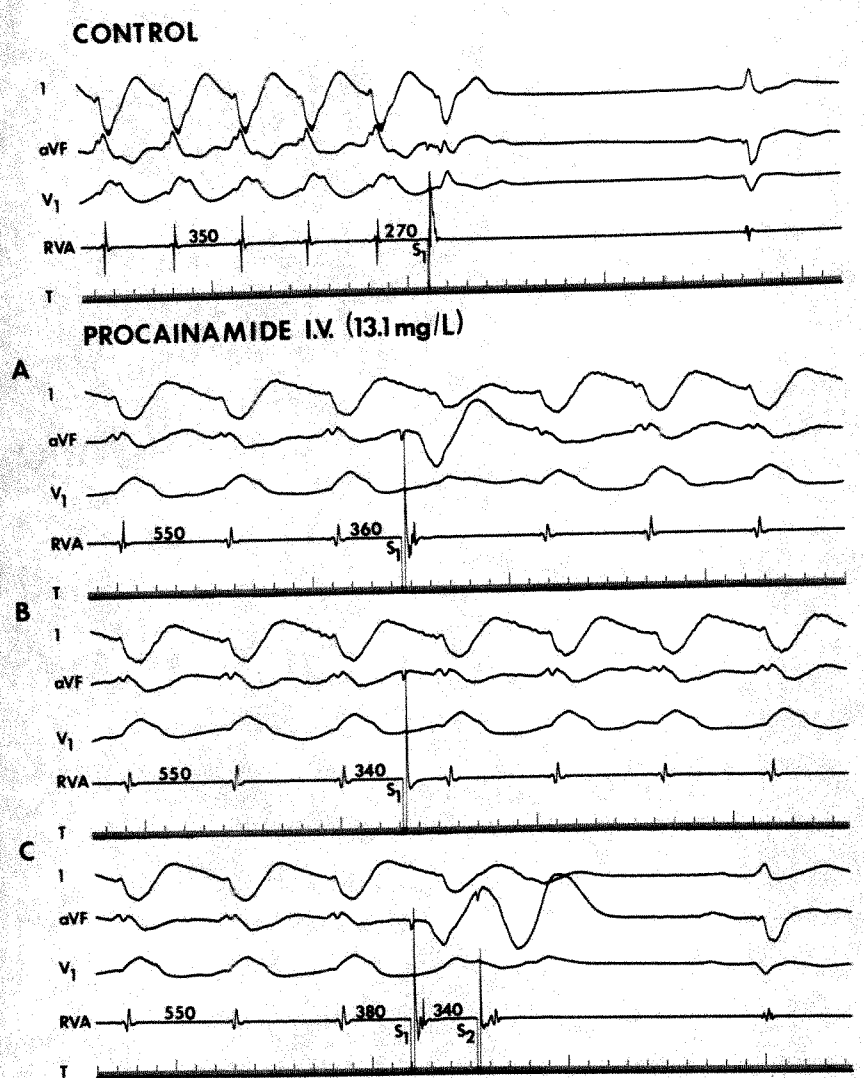

FIGURE 1. Control: VT with a cycle length of 350 ms is terminated by a single ventricular extrastimulus delivered at 270 ms before procainamide administration. Procainamide (13.1 mg/liter): **Panel A,** after procainamide administration the tachycardia cycle length has increased to 550 ms. A single ventricular extrastimulus introduced at 360 ms fails to terminate tachycardia. **Panel B,** prolongation of ventricular refractoriness by procainamide prevents a single ventricular extrastimulus delivered at 340 ms from capturing the ventricle. **Panel C,** 2 ventricular extrastimuli at 380 and 340 ms are required to terminate VT after procainamide. In each panel surface leads I, aVF, and V_1 are simultaneously recorded with a right ventricular apical electrogram (RVA). T = time lines.

Discussion

Comparison with previous studies: Our data corroborate previous studies[1–5] demonstrating that pacemaker termination of VT can be performed in approximately 80% of patients. However, the mode of stimulation required to terminate VT in this study differs from that of earlier reports. In 1976 Wellens et al[1] showed that a single ventricular extrastimulus terminated induced VT in 20 of 43 patients (47%) and 2 or 3 ventricular extrastimuli were required in 13 patients (30%). An earlier report from this institution showed that VT was terminated by a single ventricular extrastimulus in 9 of 17 patients (53%), and 2 ventricular extrastimuli or rapid ventricular pacing was required in 6 patients (35%).[4]

The present study demonstrates that of 123 patients who underwent programmed ventricular stimulation during tachycardia a single ventricular extrastimulus terminated the arrhythmia in only 23 patients (19%) and that more than 1 ventricular extrastimulus or rapid ventricular pacing was required in 87 patients (71%). These observations suggest that more aggressive pacing techniques are frequently required to terminate ventricular tachycardia.

The cause for this discrepancy may be related to a change in patient population. Many of our more recent patients presented with hemodynamic collapse due in large part to faster tachycardia rates. The study by Wellens et al[1] and our earlier study[4] were largely composed of patients with a tachycardia cycle length ≥300 ms. Neither of these studies nor previous studies carefully analyzed the effect of tachycardia cycle length on various modes of termination.

Furthermore, we observed that in our patient population with VT, more aggressive stimulation is required to induce VT. Often 3 and sometimes 4 extrastimuli are required to induce tachycardia. Hence, we may be dealing with a tachycardia that has a reentrant circuit that seems more difficult to penetrate. An additional investigation on the relation between mode of initiation and mode of termination seems necessary.

Relation between tachycardia cycle length and effect of programmed stimulation: Termination of VT by single, double, or triple ventricular extrastimuli usually required a tachycardia cycle length >300 ms. Timed extrastimuli produced acceleration of VT in only a small number of patients, none of whom needed cardioversion. Rapid ventricular pacing could terminate VT in 40% of patients with cycle lengths <300 ms. However, this technique caused acceleration of the stable tachycardia in 35% of patients, a finding similar to the 43% incidence reported by Fisher et al.[3] Furthermore, most of the patients (13 of 19) with this complication required cardioversion because of rapid hemodynamic deterioration. Although rapid ventricular pacing techniques can be useful and their complications can be rapidly corrected in the electrophysiologic laboratory, we believe that because acceleration or degeneration to ventricular fibrillation is not uncommon, this mode of stimulation should be rarely employed, if at all, for chronic pacemaker therapy of VT.

Effect of procainamide on termination of VT: Wellens et al[7] showed that drugs that can slow the tachycardia can also facilitate termination. This finding was true in 44% of our 23 patients in whom we could study the mode of termination before and after procainamide administration. However, this drug made termination more difficult in 26% of our patients. The plasma level of procainamide or tachycardia cycle length was not a useful predictor of the effects on termination. Several factors can influence the ability to terminate VT: tachycardia cycle length, site of stimulation in relation to the site of tachycardia circuit, and ventricular conduction and refractoriness.[1–4] Modifications of these factors by pharmacologic agents, stimulation at different sites, or increasing the current strength can influence the ability of an impulse to reach the reentrant circuit at a critical time to terminate the arrhythmia. Although modification of tachycardia cycle length by procainamide favors facilitation of termination, the increased ventricular refractoriness and prolonged intraventricular conduction produced by the drug can make termination more difficult (Fig. 1). The interplay of these factors will determine the effect of procainamide on tachycardia termination. Previous investigators have shown variable effects on reentrant tachycardia and ventricular tissue with procainamide.[7,8] Our demonstration of poor correlation between cycle length slowing by procainamide and termination of VT supports these earlier observations and suggests that the effect of procainamide on intraventricular conduction and refractoriness may be a more important factor. Therefore, increasing the tachycardia cycle length with drugs does not necessarily assure that pacemaker termination will be facilitated. Thus, the potential value of pacemaker and drug combination requires individual evaluation.

Limitations: Although our patient population is the largest heretofore reported, it probably represents a selected subgroup of patients with more refractory ventricular arrhythmia. Extrapolation of our findings to other patient populations may not be appropriate. In addition, because of the retrospective format of this study, there are methodologic limitations such as nonuniformity of stimulation protocol. Moreover, all methods of stimulation were not studied in each patient because of the speed with which termination was required clinically and the various staff members performing the studies. Another limitation of the present study is the use of the right ventricle usually apex or low septum as the stimulating site in this study. Changing the pacing site to the right ventricular outflow tract or the left ventricle might have produced different results, particularly after procainamide. However, because most permanent pacemakers are implanted at the right ventricular apex, our observations may still have clinical relevance. Another limitation is that stimulation was performed at twice the diastolic threshold which was

always less than 2 mA. Most permanent pacemakers deliver between 5 and 10 mA, so that our study may underestimate the ability of less aggressive stimulation to terminate the tachycardia. A recent observation from our laboratory has demonstrated that termination of VT by 1 or 2 ventricular extrastimuli can be facilitated by increasing the current strength to 5 to 10 mA.[9]

Conclusions: We believe that the following conclusions can be helpful to the clinician in performing electrophysiologic testing of patients with VT and in selecting a proper mode of termination when right ventricular stimulation is employed: (1) In approximately 80% of patients in whom VT can be induced the arrhythmia can be terminated by programmed ventricular stimulation. (2) Termination by timed extrastimuli usually requires a tachycardia cycle length >300 ms. (3) In patients with tachycardia cycle length <300 ms, rapid ventricular pacing or cardioversion is usually required to terminate the arrhythmia. (4) When performing rapid ventricular pacing, the clinician should be alert to the possible acceleration of tachycardia which can occur in over one third of patients. Therefore, we do not recommend that this mode of stimulation be employed for chronic pacemaker therapy of VT. (5) Although procainamide can slow the tachycardia and facilitate termination, it can make termination more difficult in 1 of 4 patients. This potential problem should be tested before treating a patient with a combination of drug therapy plus a pacemaker.

MICROENCAPSULATION:

Liquid potassium release from micro-encapsulated KCl crystals, and a special dispersing agent to minimize the likelihood of high local concentrations. Plus the solid convenience of a taste-free capsule, to promote long-term compliance.

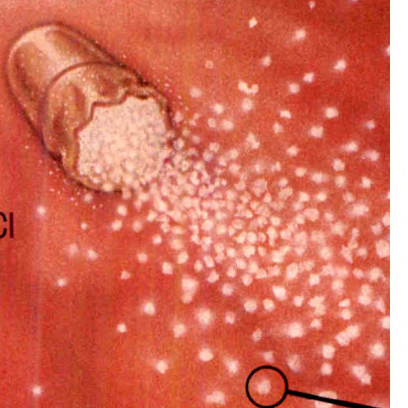
THAT'S MICRO-K®*

(Potassium Chloride)

*For patients who cannot tolerate or refuse to take liquid preparations.

The potassium supplement you can prescribe with confidence.

DISPERSION



1. Convenient taste-free capsule dissolves, releasing 10,000 individually coated KCl crystals.

2. Unique dispersing agent spreads these microcapsules throughout the G.I. tract, minimizing likelihood of ulceration due to high localized concentrations. *(Please see Warnings and Contraindications sections of prescribing information.)*

LIQUID POTASSIUM RELEASE PLUS SOLID DOSAGE BENEFITS

A SUPERIOR KCl DELIVERY SYSTEM

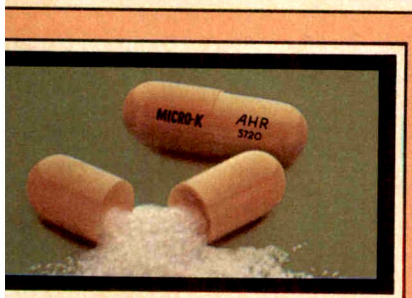
DIFFUSION

3. Liquid-permeable coating around each individual crystal protects mucosa from contact with solid potassium.

4. Diffusion of liquid KCl with controlled 8-10 hour release begins when gastrointestinal fluid permeates coating to dissolve KCl crystal inside.

5. Pharmacologically inert coating is excreted.

Artist's rendering of Micro-K dispersion in G.I. tract.



MICRO-K®

(Potassium Chloride)

Controlled-Release Extencaps® 8 mEq

LIQUID POTASSIUM RELEASE PLUS SOLID DOSAGE BENEFITS

MICRO-K®
(Potassium Chloride)
Controlled-Release Extencaps® 8 mEq

- Convenient taste-free capsule
- 10,000 individually coated crystals
- Special dispersing agent, to minimize high local concentrations
- Diffusion of liquid KCl over 8-10 hours

Prescribing Information

Description: Micro-K Extencaps are hard gelatin capsules, each containing 600 mg of dispersible small crystalline particles of potassium chloride (equivalent to 8 mEq K). Each particle is microencapsulated with a polymeric coating which allows for controlled release of potassium and chloride ions over an eight- to ten-hour period. The dispersibility of the microcapsules and the controlled release of ions are intended to minimize the likelihood of high localized concentrations of potassium chloride and resultant mucosal ulceration within the gastrointestinal tract.

The polymeric coating forming the microcapsules functions as a water-permeable membrane. Fluids pass through the membrane and gradually dissolve the potassium chloride within the microcapsules. The resulting potassium chloride solution slowly diffuses outward through the membrane.

Actions: Potassium ion is the principal intracellular cation of most body tissues. Potassium ions participate in a number of essential physiological processes, including the maintenance of intracellular tonicity, the transmission of nerve impulses, the contraction of cardiac, skeletal, and smooth muscle and the maintenance of normal renal function.

Potassium depletion may occur whenever the rate of potassium loss through renal excretion and/or loss from the gastrointestinal tract exceeds the rate of potassium intake. Such depletion usually develops slowly as a consequence of prolonged therapy with oral diuretics, primary or secondary hyperaldosteronism, diabetic ketoacidosis, severe diarrhea, or inadequate replacement of potassium in patients on prolonged parenteral nutrition. Potassium depletion due to these causes is usually accompanied by a concomitant deficiency of chloride and is manifested by hypokalemia and metabolic alkalosis. Potassium depletion may produce weakness, fatigue, disturbances of cardiac rhythm (primarily ectopic beats), prominent U-waves in the electrocardiogram, and in advanced cases, flaccid paralysis and/or impaired ability to concentrate urine.

Potassium depletion associated with metabolic alkalosis is managed by correcting the fundamental causes of the deficiency whenever possible and administering supplemental potassium chloride, in the form of high potassium food or potassium chloride solution, capsules or tablets. In rare circumstances (e.g., patients with renal tubular acidosis) potassium depletion may be associated with metabolic acidosis and hyperchloremia. In such patients potassium replacement should be accomplished with potassium salts other than the chloride, such as potassium bicarbonate, potassium citrate, or potassium acetate.

INDICATIONS: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases, supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia.* In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.

The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustments.

Interaction with Potassium-Sparing Diuretics. Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions. Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths, in addition to upper gastrointestinal bleeding. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation.

Micro-K Extencaps contain microcapsules which disperse upon dissolution of the hard gelatin capsule. The microcapsules are formulated to provide a controlled release of potassium chloride. The dispersibility of the microcapsules and the controlled release of ions from the microcapsules are intended to minimize the possibility of a high local concentration near the gastrointestinal mucosa and the ability of the KCl to cause stenosis or ulceration. Other means of accomplishing this (e.g., incorporation of KCl into a wax matrix) have reduced the frequency of such lesions to less than one per 100,000 patient years (compared to 40–50 per 100,000 patient years with enteric-coated KCl), but have not eliminated them. The frequency of GI lesions with Micro-K Extencaps is, at present, unknown. Micro-K Extencaps should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis. Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and may be minimized by taking the dose with meals or by reducing the dose.

Intestinal bleeding, ulceration, perforation and obstruction have been reported in patients treated with solid dosage forms of potassium salts and may occur with Micro-K Extencaps (see Contraindications and Warnings).

One of the most severe adverse effects of potassium supplementation is hyperkalemia (see Contraindications, Warnings, and Overdosage).

Skin rash has been reported rarely with potassium preparations.

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiogram changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following: (1) elimination of foods and medications containing potassium and of potassium-sparing diuretics; (2) intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10–20 units of insulin per 1,000 ml; (3) correction of acidosis, if present, with intravenous sodium bicarbonate; (4) use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Dosage and Administration: The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient, but typically is in the range of 2 to 3 Micro-K Extencaps per day (16 to 24 mEq K) for the prevention of hypokalemia and 5 to 12 Micro-K Extencaps (40 to 96 mEq K) or more per day for the treatment of potassium depletion. If more than 2 Micro-K Extencaps are prescribed per day, the total daily dosage should be divided into two or more separate doses.

How Supplied: Pale orange capsules (Extencaps), each containing 600 mg microencapsulated potassium chloride (equivalent to 8 mEq K) in bottles of 100 (NDC 0031-5720-63), and 500 (NDC 0031-5720-70) and Dis-Co® unit dose packs of 100 (NDC 0031-5720-64).

Animal Toxicology: The ulcerogenic potential of microencapsulated KCl was studied in anesthetized cats by direct applications on exteriorized gastric mucosa. The microcapsules of KCl were found to be non-ulcerogenic and significantly less irritating than wax-matrix tablets and 20% solution of KCl.

In groups of monkeys (up to 8 monkeys per group) receiving different formulations of potassium chloride at equivalent daily dosage (2400 mg KCl) for four and one-half days, Micro-K Extencaps showed no tendency to cause intestinal ulceration (similar to liquid KCl and a wax-matrix preparation but in contrast to an enteric-coated KCl tablet) and minimal gastric irritation (less than a wax-matrix preparation).

Critical Pattern Recognition.™ The next wave in Holter data analysis.

DEL MAR AVIONICS

No two patients have exactly the same ECG waveforms.

So to give you the most precise data analyzer for processing Holter tapes, we offer Critical Pattern Recognition.

Both the Trendsetter™ and Evaluator™ Data Analysis Systems are computer-controlled to recognize normal and variant ECG waveforms for each individual patient.

Waveforms are categorized, counted and compared to the patient's typical ECG, even though these normal patterns may vary throughout the monitoring period.

Moreover, analysis is halted automatically upon occurence of significant ectopic patterns, such as paired VEs/SVEs, R-on-T, V-Tach, SV-Tach, Ventricular Bigeminy, Bradycardia beats/runs and other critical events.

Dual 12-in CRT displays provide unsurpassed control of real-time data. And a wide selection of report formats (alphanumerics, graphics and analog trends) provide comprehensive permanent data for improved patient management.

Additionally, the Trendsetter can be updated to accommodate blood pressure, pacemaker analysis, dual floppy disks and other options. Choose only what you need now and add more capability later.

For more details on the first Holter data analysis systems to offer Critical Pattern Recognition, call or write: Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

Trendsetter and Evaluator are trademarks, Del Mar Avionics.

The ECG cartridge with 50 lives.

DEL MAR AVIONICS

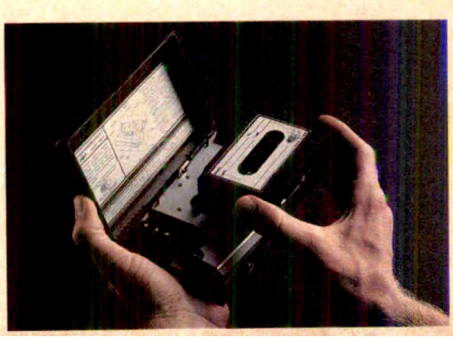
Conventional 24-hour Holter reel tapes have less than 9 lives. And cassettes are recommended only for single use.

But our advanced design, four-channel cartridge, when used with the Series 449 Electrocardiocorder® Systems, may be erased and re-used for up to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically designed with extended tape life in mind. Combining the convenience of a cassette with the accuracy of a reel-to-reel design, the cartridge tape can be manipulated at today's high scanning speeds with exact precision. Moreover, precise data management can be attained without tape stretching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.



And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine California 92714. Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

Two-Dimensional Echocardiographic Assessment Of Dextrocardia: A Segmental Approach

JAMES C. HUHTA, MD, DONALD J. HAGLER, MD, JAMES B. SEWARD, MD, ABDUL J. TAJIK, MD, PAUL R. JULSRUD, MD, and DONALD G. RITTER, MD

Two-dimensional echocardiography was used in the prospective evaluation of 40 patients with the clinical diagnosis of dextrocardia. A segmental analysis of the situs, connections, ventricular anatomy, and chamber positions was utilized for a complete diagnostic assessment. An adequate examination was possible in 33 of these patients; the findings were confirmed by cardiac catheterization and angiography in 31 patients and at operation in 26.

Use of the location of the liver and the drainage of the hepatic veins and inferior vena cava allowed atrial visceral situs to be defined in 33 patients (solitus 21, inversus 9, and ambiguous 3). Pulmonary venous connections were correctly identified in 27. In 33 patients, atrioventricular (AV) and ventriculoarterial connections and ventricular anatomy were correctly predicted. Twenty patients had 2 separate well-developed ventricles. Ventriculoarterial connections were determined correctly in all 20 patients: concordant in 5, discordant in 6, double-outlet right ventricle in 5, and single-outlet right ventricle (pulmonary atresia) in 4. In 16 patients a ventricular septal defect was correctly identified. In the remainder the ventricular septum was intact.

Thirteen patients had univentricular heart: 8 had 2 AV valves (double-inlet ventricle), 3 had common AV inlet, and 2 had atresia of 1 AV connection.

Two-dimensional echocardiography allowed the accurate assessment of complex congenital heart defects associated with dextrocardia. Utilizing a segmental approach, one can correctly predict atrial-visceral situs, ventricular morphology and situs, and AV and ventriculoarterial connections.

Two-dimensional echocardiography has substantially expanded the horizons for accurate noninvasive diagnosis of congenital cardiac defects. A number of reports have demonstrated the utility of 2-dimensional echocardiography in diagnosing complex forms of congenital heart disease, such as transposition of the great arteries, double-outlet right ventricle, univentricular heart, and AV discordance.[1–6] Analysis of complex congenital cardiac anatomy requires an organized and detailed approach. Cardiac pathologists have emphasized the importance of a logical sequential or segmental approach in the analysis of multiple complex congenital heart lesions involving abnormalities of chamber position and connections.[7–10] These methods have been expanded to allow the premortem diagnosis of such lesions, using cardiac catheterization and biplane angiographic techniques.[11] M-mode echocardiographic studies have attempted such correlation,[12,13] but it is only with the advent of 2-dimensional echocardiography that a noninvasive segmental analysis of cardiac anatomy has been feasible.

Dextrocardia is a condition in which the major axis of the heart (base to apex) points to the right, not as a consequence of acquired disease but as a result of congenital malposition.[7,11] Dextrocardia may exist with situs solitus, situs inversus, or situs ambiguous. Because a broad spectrum of cardiac anomalies may accompany dextrocardia, this group of anomalies appears to represent a critical test of the segmental approach for the 2-dimensional echocardiographic assessment of complex congenital heart disease. After our review of patients with AV discordance,[6] it was apparent that a segmental approach was necessary for the accurate and

From the Mayo Clinic and Mayo Foundation, Rochester, Minnesota. Manuscript received March 1, 1982; revised manuscript received May 27, 1982, accepted June 18, 1982.

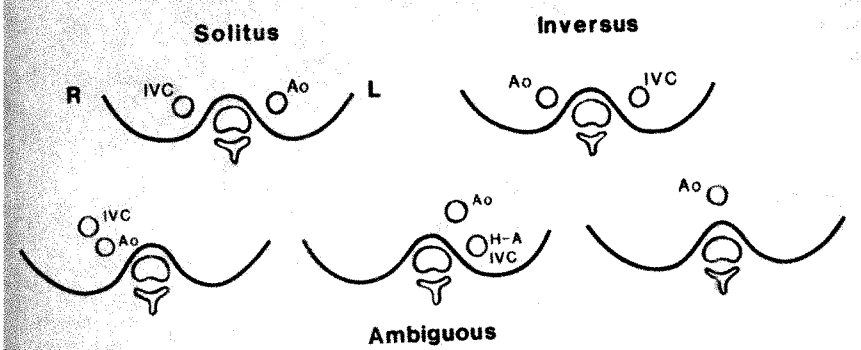

FIGURE 1. Drawing illustrating the respective orientations of the inferior vena cava and the abdominal aorta relative to the spine in situs solitus, situs inversus, and situs ambiguous. In situs ambiguous, the inferior vena cava (IVC) and aorta (Ao) tend to lie on the same side of the spine, or the inferior vena cava may not be visualized. A vascular structure posterior to the aorta may represent an azygous or hemizygous continuation (H-A) with interrupted inferior vena cava.

thorough diagnosis of complex congenital heart disease. We utilized the approach proposed with that study to analyze patients who had a clinical diagnosis of dextrocardia (Table I).

Methods

Between October 1977 and November 1981, 40 patients with the clinical diagnosis of dextrocardia were examined by 2-dimensional echocardiography. Seven patients were subsequently excluded because the examinations were not technically adequate to define the situs or the details of intracardiac anatomy. Of the remaining 33 patients, the results of cardiac catheterization and angiography were available in 31, and surgical confirmation of the cardiac anatomy was available in 26. In 2 patients with isolated dextrocardia, 2-dimensional echocardiography revealed normal cardiac anatomy, and no further evaluation or treatment was deemed necessary. The ages of the patients at the time of examination ranged from 2 days to 29 years, with a mean of 8.5 years. Thirteen patients previously had palliative surgery, including Glenn and Blalock-Taussig shunts. One patient had previous intracardiac surgery, with closure of a ventricular septal defect and mitral valve replacement.

TABLE I Segmental Approach for Prospective 2-Dimensional Echocardiographic Study of Complex Congenital Heart Disease

1. Atrial and visceral situs
   - Caval position and connection
   - Hepatic veins
   - Coronary sinus
   - Pulmonary venous connection
2. AV connections and AV valve morphology
   - Commitment (AV malalignment-overriding, criss-cross)
   - Insertion (chordal attachment-straddling)
   - Leaflet numbers
   - Papillary muscles (position, number, abnormality-parachute)
   - Leaflet abnormalities (cleft, thickening-stenosis)
3. Ventricular situs and morphology
   - Cardiac position (levocardia, dextrocardia, mesocardia)
   - Ventricular relations (anterior, posterior, superior, inferior, right, left)
   - AV valve attachment
   - Shape (ellipsoid, crescentic, triangular)
   - Trabecular pattern
   - Papillary muscles (2 discrete versus multiple irregular)
4. Great artery relations
   - Position (normal, side-by-side, dextro, levo)
   - Ventriculoarterial connection
   - Override
   - AV valve continuity (subvalvular conus)
   - Identification
     - Posterior course and bifurcation of pulmonary artery
     - Anterior and superior course of aorta

Reprinted, with permission, from Hagler et al.[6]

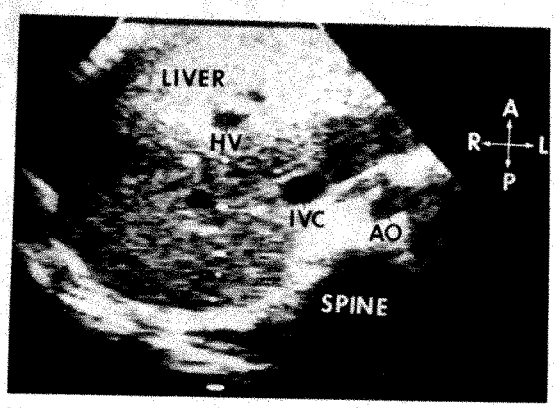
Two-dimensional echocardiographic examinations were performed using the Varian 3000, Varian 3400, or the American Technology Laboratory (Mark V) wide-angle sector echocardiograph. The examinations were carried out with the knowledge that the patients had dextrocardia, as determined by standard posteroanterior chest roentgenogram. The patients were examined using left parasternal long- and short-axis views, right parasternal long- and short-axis views, right apical and subcostal long-axis and 4-chamber views, and suprasternal long- and short-axis views. The right parasternal long- and short-axis scans were obtained utilizing right parasternal transducer positions similar to those used in left parasternal scans. The transducer orientation was maintained to achieve image orientation similar to that in the standardized left parasternal views, that is, superior and leftward structures observed on the right of the video image. Similarly, for apical and subcostal views, image orientation was maintained to keep leftward structures located on the right of the video image. We emphasize that if cardiac structures cannot be adequately seen from 1 position, alternate scans from multiple and atypical positions should be employed. Apical 4-chamber and subcostal 4-chamber long- and short-axis views must be included in the examination.

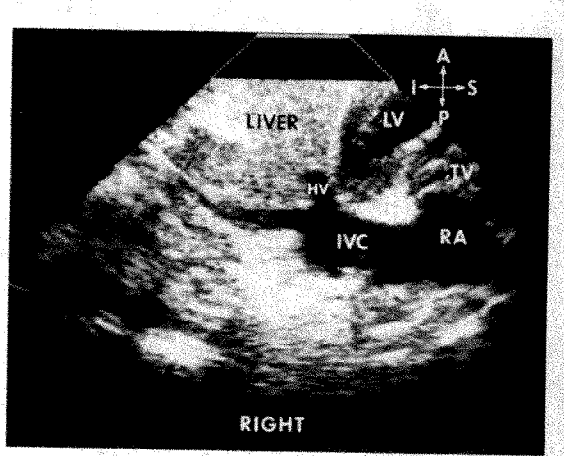
After our initial experience in examining such patients, left parasternal long- and short-axis views were found particularly helpful in some cases in delineating great artery relations. Subcostal and apical 4-chamber long-axis views are helpful in delineating ventricular morphology and AV and ventriculoarterial relations. Subcostal scans were frequently utilized because of the retrosternal position of cardiac structures. Transducers of 2.25, 3, and 3.5 MHz were employed, depending on the instrument used and the patient size. At the time of this review, without knowledge of the details of the previous examination, the recorded videotapes were independently examined and an assessment was made using the segmental method described. After this review, the results were compared with the original 2-dimensional echocardiographic reports, and a combined data base was obtained; this was then compared with the angiographic and surgical findings. Photographs (35 mm) were obtained of the stop-action video images.

Results

Anatomic 2-dimensional echocardiographic findings and the comparison with angiographic observations are shown in Tables II to IV. As described, an adequate 2-dimensional echocardiographic examination was successfully obtained in 33 of 40 patients (83%).

Atrial-visceral situs: Atrial and visceral situs was determined by 2-dimensional echocardiography, primarily using the location of the liver and the hepatic,





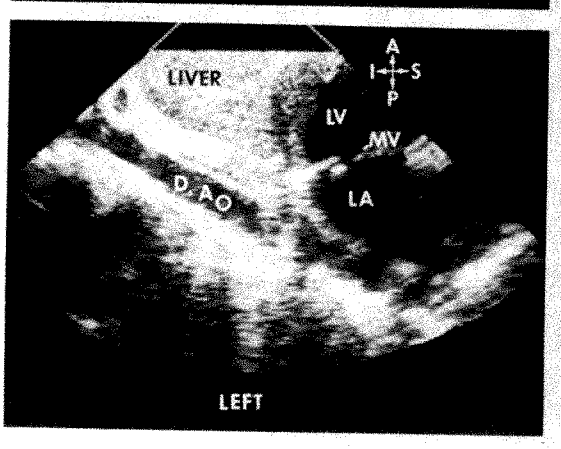


FIGURE 2. Subcostal short-axis (**top left**) and long-axis (**top right and bottom**) scans of inferior vena cava (IVC) and aorta (AO) demonstrate atrial visceral situs. **Top left,** subcostal short-axis scan of the abdomen in 4-month-old boy with situs solitus and isolated dextrocardia. Note that the mass of the liver, hepatic veins (HV), and inferior vena cava lie to the right of the spine while the descending thoracic aorta is visualized slightly to the left. **Top right,** long-axis scan with transducer angulation to the right of the spine demonstrates inferior vena cava and its connection to systemic venous atrium, which is located on the right in 9-year-old patient with situs solitus and isolated dextrocardia. Note that inferior vena cava courses posterior to the body of left ventricle (LV) in order to reach morphologic right atrium (RA). TV = tricuspid valve. **Bottom,** with transducer angulation to the left of the spine, descending abdominal aorta (D.AO) is demonstrated. In addition, the morphologic left atrium (LA) on the left is observed. A separate left atrioventricular valve and the morphologic mitral valve (MV) are also visualized connecting to the morphologic left ventricle. A = anterior; I = inferior; P = posterior; S = superior.

venous, and inferior vena caval connections. Pulmonary venous drainage to the left atrium and coronary sinus drainage, when identified, were used as supportive (secondary) criteria. Atrial-visceral situs was determined by 2-dimensional echocardiography as solitus, inversus, or ambiguous. Once the diagnosis of situs ambiguous was established, no further attempts were made to differentiate atrial situs or morphology based on systemic or pulmonary venous connections.

Atrial-visceral situs solitus was diagnosed when the major portion of the liver, the hepatic veins, and the inferior vena cava were visualized to the right of the spine on short-axis subcostal scans of the abdomen. In addition, the descending abdominal aorta was noted to the left of the spine (Fig. 1 and 2). During a real-time observation, the aorta can be identified by its systolic pulsation and its thicker arterial wall. On long-axis scan with transducer angulation to the right, the inferior vena cava may be observed. Such a long-axis scan of the inferior vena cava demonstrated the hepatic venous connection to the inferior vena cava and the subsequent course of the inferior vena cava to the morphologic right atrium (Fig. 2, top right). A long-axis scan with transducer angulation to the left demonstrated the descending abdominal aorta (Fig. 2, bottom).

Atrial situs inversus was diagnosed when the major portion of the liver, hepatic veins, and inferior vena cava were visualized to the left of the spine on short-axis subcostal scans of the abdomen. In a mirror-image fashion, the descending abdominal aorta was noted to the right of the spine (Fig. 1 and 3). Developing a long-axis scan of the inferior vena cava with transducer angulation to the left emphasized the leftward position of the liver and the hepatic venous connection to the inferior vena cava. The subsequent course of the inferior vena cava was then demonstrated superiorly and to the left-sided systemic venous atrium, the morphologic right atrium (Fig. 3, bottom).

Situs ambiguous was identified when the mass of the liver was midline, equally distributed to the right and to the left.[14] In such cases, the inferior vena cava and abdominal aorta tend to lie on the same side of or directly anterior to the spine, with the inferior vena cava running anterior to the aorta[15] (Fig. 1 and 4). In some cases of situs ambiguous (usually polysplenia), a portion of the inferior vena cava is absent or the inferior vena cava cannot be visualized; in other cases, a hemizygous venous system may be posterior to the aorta but on the same side of the spine (Fig. 4, middle and bottom). Once the diagnosis of situs ambiguous has been established, other noninvasive means may be used to further assess the type—either asplenia or polysplenia.[16]

In this series, 21 of the 33 patients had situs solitus (64%), 9 had situs inversus (27%), and 3 had situs ambiguous (9%). Findings on 2-dimensional echocardiography, cardiac catheterization, and angiography were in agreement in the assignment of situs in all 33.

Apical and subcostal 4-chamber views were used to demonstrate pulmonary venous drainage to the morphologic left atrium and drainage of the coronary sinus

TABLE II Two-Dimensional (2-D) Echocardiography, Segmental Analysis, and Angiographic Correlation in Solitus Group

Case	Sex & Age	AV Con-nection	Ventricular Morphology	Relation of Ventricles and of Rudimentary Pouch to Main Chamber	Ventriculo-arterial Connection	Relation of Arteries (Aorta Position)	Associated Anomalies Defined by 2-D Echo	Angiographic Correlation

to the morphologic right atrium (Fig. 5). These observations were available as supportive or secondary criteria for recognition of atrial situs. The pulmonary venous connection was correctly identified in 27 of the 33 patients.

Suprasternal scans were used to identify a right- or left-sided superior vena cava, other anomalies of the systemic venous drainage, the drainage of the right pulmonary veins to the left atrium, and the position of the aortic arch. High right parasternal long-axis and subcostal views were employed to demonstrate drainage of the superior vena cava to the right atrium.

Figure 6 (top) demonstrates a normal right superior vena cava in a patient with situs solitus, and Figure 6 (bottom) shows bilateral superior venae cavae in a patient with situs inversus.

AV connection and ventricular morphology: Further assessment of AV connections requires determination of the ventricular morphology. Recently, we

FIGURE 3. Subcostal short-axis (**top**) and long-axis (**bottom**) scans of the abdomen in a 14-year-old patient with situs inversus demonstrate the mass of the liver, hepatic veins (HV,) and inferior vena cava (IVC) coursing to the left of the spine while the abdominal aorta (AO) is observed on the right. A partial long-axis scan (**bottom**) of the inferior vena cava is developed, emphasizing the leftward position of the hepatic venous connection and also the superior course and subsequent drainage of the inferior vena cava into the systemic venous atrium on the left (the morphologic right atrium [RA]).

TABLE III Two-Dimensional (2-D) Echocardiography Segmental Analysis and Angiographic Correlation in Inversus Group

Case	Sex & Age	AV Con-nection	Ventricular Morphology	Relation of Ventricles and of Rudimentary Pouch to Main Chamber	Ventriculo-arterial Connection	Relation of Arteries (Aorta Position)	Associated Anomalies Defined by 2-D Echo	Angiographic Correlation

Ant. = anterior; ASD = atrial septal defect; AVV = AV valves; Con = concordant; DI = double-inlet; Dis = discordant; DO = double-outlet; lt = left; LV = left ventricle; MV = mitral valve; post. = posterior; PS = pulmonary stenosis; rt = right; RV = right ventricle; SI = single-inlet; SO = single-outlet; sup.-inf. = superior-inferior; SVC = superior vena cava; UVH = univentricular heart; VSD = ventricular septal defect.

described the 2-dimensional echocardiographic criteria that were employed to determine ventricular morphology.[6] These criteria require assessment of the AV valve morphology (bileaflet versus trileaflet) (Fig. 7, top), the relative points of attachment of the AV valves to the ventricular septum (the morphologic tricuspid valve attaches lower along the ventricular septum), the presence of 2 papillary muscles for the morphologic left ventricle, and a coarse, heavily trabecular pattern and AV semilunar valve discontinuity for the morphologic right ventricle (Fig. 7, bottom). Thus, in those patients in whom the morphologic right atrium (as determined by atrial situs) connected to the morphologic right ventricle, the AV connection was concordant (Fig. 7, bottom). When the right atrium connected to the morphologic left ventricle, the AV connection was discordant. In this series, 20 patients had 2 separate and well-developed ventricular chambers that could be identified. The morphologic left ventricle was noted to the left and anterior in 6 and to the right and posterior in 14. In 16 patients, a single ventricular septal defect was correctly identified, and in the remaining patients, the ventricular septum was intact.

In all 33 patients, the AV connection was correctly determined. Of the 20 patients with 2 distinct ventricles, 12 had atrial situs solitus, 5 with a concordant AV connection and 7 with a discordant AV connection. Seven patients had atrial situs inversus, and the AV connection was concordant in 6 and discordant in 7. In 1 patient, the atrial situs was ambiguous, with a common AV connection by way of a common AV valve.

Thirteen patients had univentricular heart, 8 with 2 AV valves (double-inlet ventricle), 3 with common AV inlet, and 2 with atresia of 1 AV connection. Two of these patients had situs ambiguous (1 with polysplenia and 1 with asplenia). Four patients had a univentricular heart with an outlet chamber (presumably the anatomic left ventricular type univentricular heart). Three had an outlet chamber that was anterior and to the left. In 1 patient with situs solitus and atretic right AV connections (tricuspid atresia), an outlet chamber was noted posterior and to the right. In 3 patients, a univentricular heart with a rudimentary pouch was observed (presumably the anatomic right ventricular type univentricular heart). In 2, the rudimentary pouch was demonstrated posterior and to the right of the main chamber, and in 1, the pouch was anterior and to the left. In the remaining patients with univentricular heart, the ventricular morphology was indeterminate and a rudimentary or outlet chamber could not be adequately demonstrated echocardiographically.

Ventriculoarterial connections: The ventriculoarterial connections were determined echocardiographically by parasternal long- and short-axis scans (Fig. 7, bottom) and by subcostal long-axis scans (Fig. 8). Identification of the great arteries was based on recognition of the posterior course and early bifurcation of the pulmonary artery and the superior and more anterior course of the aorta. The ventriculoarterial connections were correctly identified in all 20 patients with 2 ventricles. They were concordant in 5 and discordant in 6; 5 patients had double-outlet right ventricle, and 4 had single-outlet (pulmonary atresia) right ventricle. Of the total group, 11 patients were considered to have a single outlet, and pulmonary valve atresia was suspected on the basis of the inability to identify the pulmonary valve or to recognize pulmonary valve motion. Pulmonary valve atresia was confirmed angiographically in 10 of these patients. The relation of the great arteries was not defined in 4 patients with sin-

TABLE IV Two-Dimensional (2-D) Echocardiography Segmental Analysis and Angiographic Correlation in Ambiguous Group

Case	Age (yr) & Sex	AV Connection	Ventricular Morphology	Relation of Ventricles and of Rudimentary Pouch to Main Chamber	VA Connection	Relation of Arteries (Aorta Position)	Associated Anomalies Defined by 2-D Echo	Angiographic Correlation
1	10 M	Common AVV (ambiguous)	2 ventricles	LV to rt post. and inf. of RV	DO RV	Rt, ant.	Common atrium, common AVV, azygous continuation of rt-sided IVC, pulmonary stenosis	LAD coronary arises from rt coronary artery, asplenia
2	6 M	Common AVV (DI)	UVH	Pouch post. and to rt of MC	DO MC	Lt, ant.	Common AV valve, chordae inserting in pouch, azygous continuation of IVC, bilateral SVC, severe PS	Same, polysplenia
3	3 M	Common AVV (DI)	UVH	Pouch post. and to rt of MC	DO MC	Lt, ant.	Common atrium, common AV valve, bilateral SVC, severe PS	Same, previous lt subclavian to lt pulmonary artery and aorta to rt pulmonary artery anastomosis, asplenia

Ant. = anterior; AVV = AV valves; DI = double-inlet; DO = double-outlet; inf. = inferior; IVC = inferior vena cava; LAD = left anterior descending; lt = left; LV = left ventricle; MC = main chamber; post. = posterior; PS = pulmonary stenosis; rt = right; RV = right ventricle; SVC = superior vena cava; UVH = univentricular heart; VA = ventriculoarterial.

gle-outlet ventricle, but the relative position of the great arteries was correctly identified in the remaining 29 patients.

Associated anomalies: Ventricular septal defect was the most common associated anomaly and was present in 16 of the 20 patients who had 2 separate ventricles. The presence of a ventricular septal defect was confirmed by angiography in all 16. Multiple associated muscular ventricular septal defects were identified angiographically in 1 patient. Two-dimensional echocardiography correctly identified the presence of val-

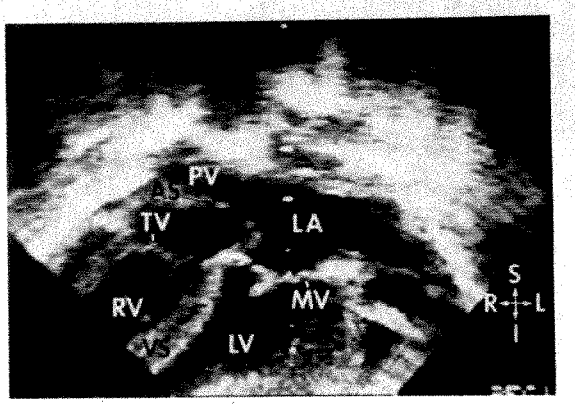

FIGURE 5. Subcostal 4-chamber view in 4-month-old patient with situs solitus and isolated dextrocardia. Pulmonary venous drainage is observed entering the morphologic left atrium (LA) on the left. Ventricular morphology is identified by relative points of insertion of AV valves. Morphologic tricuspid valve (TV) inserts at a lower position along ventricular septum (VS) than morphologic mitral valve (MV). Morphologic left ventricle (LV) has an ellipsoid configuration and a smooth-walled appearance. The left atrium connects with the morphologic left ventricle, with AV concordance. The unusual curved appearance of atrial septum (AS) is partly related to associated left juxtaposed atrial appendages observed in this patient.

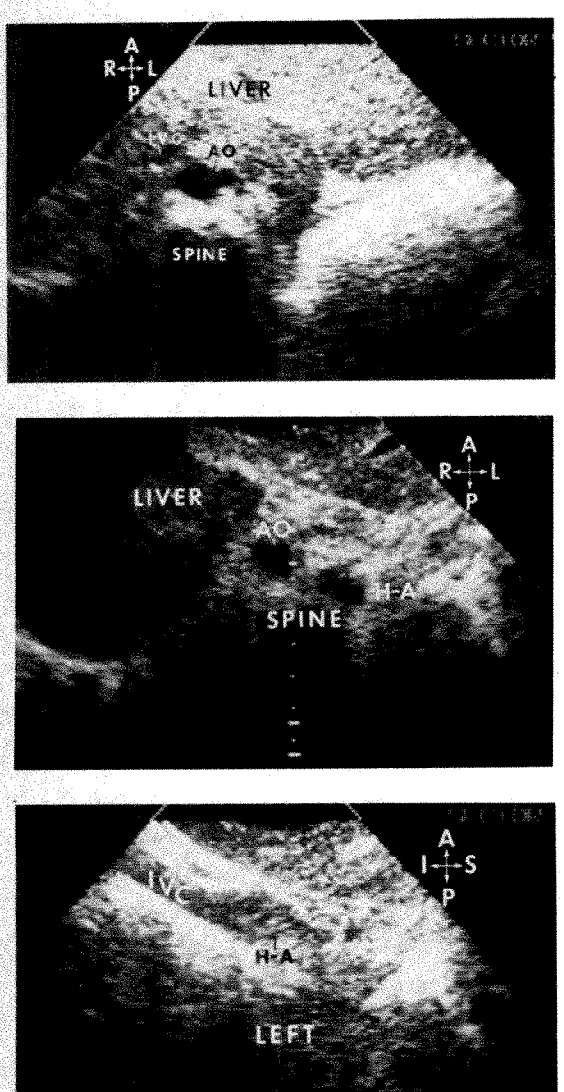

FIGURE 4. Top, subcostal short-axis scan in a patient with situs ambiguous (asplenia), demonstrating a large liver mass centrally located, with nearly equal distribution to right and left of spine. The inferior vena cava (IVC) and aorta (AO) share a central position anteriorly and on the right of the spine. **Middle,** subcostal short-axis scan in patient with situs ambiguous (polysplenia) with hemiazygous (H-A) continuation of the inferior vena cava. In this case, the liver was predominantly located on the right. The aorta was central in position, and the inferior vena cava was on the left. **Bottom,** long-axis scan of the inferior vena cava with transducer angulation to the left demonstrates the abnormal course of the IVC as it begins its hemiazygous continuation to a left superior vena cava.

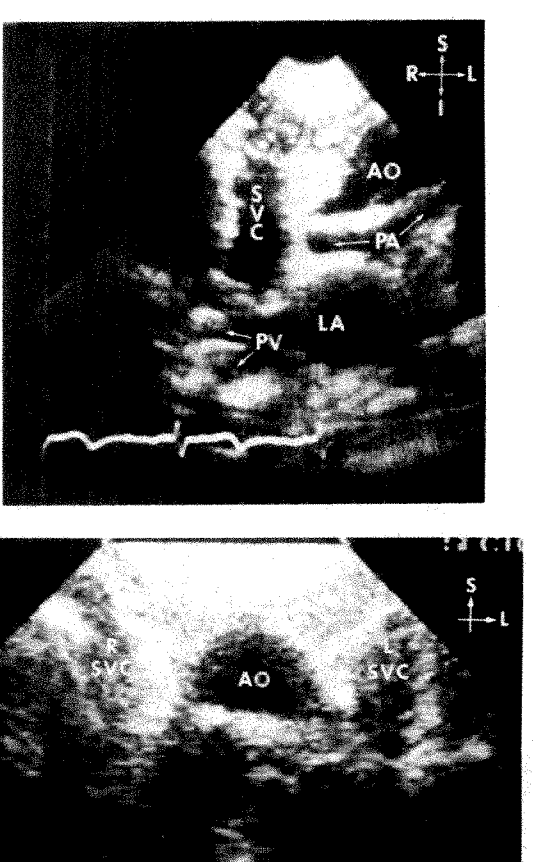

FIGURE 6. Top, suprasternal scan in patient with situs solitus, demonstrating a normally positioned superior vena cava (SVC) coursing to the right of an aortic arch (AO). In addition, inferior to right pulmonary artery (PA) are the left atrium (LA) and right pulmonary veins (PV). **Bottom,** suprasternal scan in patient with situs inversus and bilateral superior venae cavae (RSVC and LSVC). Both superior venae cavae are observed coursing in symmetrical fashion beside the aortic arch. There is no evidence of innominate venous communication between the 2 superior venae cavae.

vular or subvalvular pulmonary stenosis in 8 of the patients. Left juxtaposed atrial appendages were present in 5 patients and were recognized by 2-dimensional echocardiography in 2 of the more recent patients (Fig. 9) (Rice MJ, Seward JB, Hagler DJ, Edwards WD, Julsrud PR, Tajik AJ, submitted for publication).

Discussion

Dextrocardia is a condition in which the major axis of the heart (base to apex) points to the right.[11] The term *dextrocardia* describes only the position of the cardiac axis and does not connote any particular cardiac chamber position, connection, or abnormality. The present study shows that a wide spectrum of congenital heart disease is observed with dextrocardia and can be diagnosed noninvasively.

Segmental analysis of the cardiac anatomy has been employed in the pathologic categorization of dextrocardia by Van Praagh et al,[7] Lev et al,[8] and Calcaterra et al.[9] This method is essential in defining complex cardiac anatomy. A logical approach is to define the situs first and then the AV connection, ventricular morphology, chamber positions, ventriculoarterial connections, relation of the great arteries, and, finally, associated anomalies such as ventricular septal defect or pulmonary stenosis. The cardiac chambers are described as simply anterior or posterior, or left and right of one another. The AV connection can be concordant, discordant, double-inlet, common-inlet, or single-inlet with absence of 1 AV connection. The ventriculoarterial connection can be concordant, discordant, double-outlet, or single-outlet.

The angiographic features of dextrocardia were described by Squarcia et al,[11] thereby applying the segmental approach of dextrocardia to the premortem

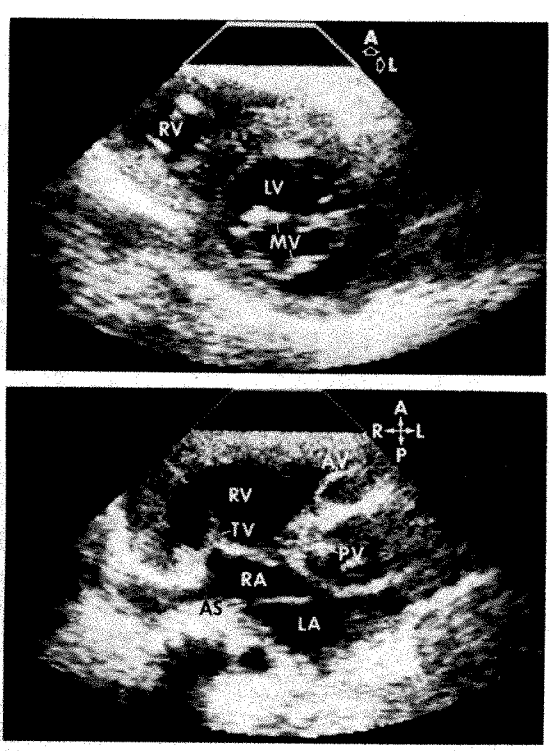

FIGURE 7. Top, short-axis scan of the heart in a 9-year-old patient with situs solitus and isolated dextrocardia. There is AV concordance with the morphologic right ventricle (RV) to the right and anterior and the morphologic left ventricle (LV) to the left and posterior. Morphologic mitral valve (MV) has a typical bileaflet appearance, whereas multiple papillary muscle attachments are observed in the apical portions of the right ventricle. **Bottom,** more superiorly near the cardiac base, the aortic valve (AV) is observed anterior to the pulmonary valve (PV). There is separation of the morphologic tricuspid valve (TV) from the anterior semilunar valve by muscular conus tissue.

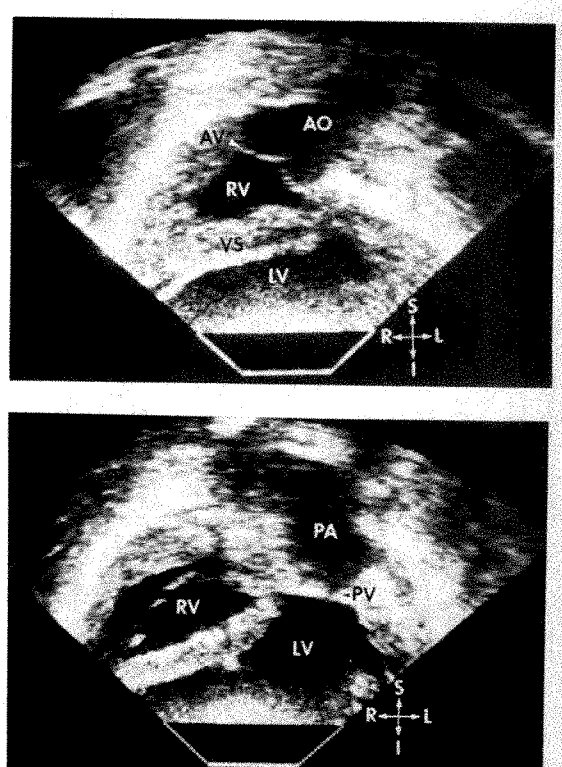

FIGURE 8. Subcostal long-axis scans in the same patient as in Figure 7 demonstrate the origin of the pulmonary artery from the morphologic left ventricle (LV), and with slightly superior transducer angulation, the aortic valve (AV) is observed originating from the morphologic right ventricle (RV)—findings consistent with ventriculoarterial discordance. The pulmonary valve is thickened and domed in this patient with pulmonary valve stenosis.

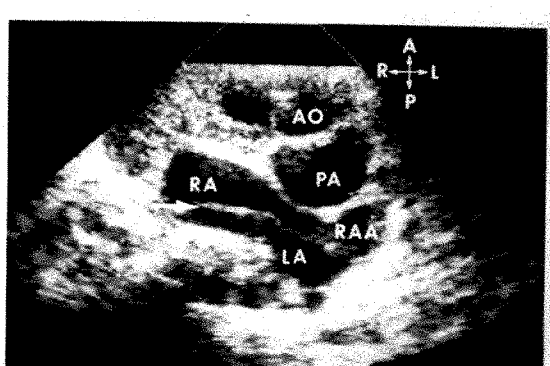

FIGURE 9. Short-axis scan in a patient with isolated dextrocardia and left juxtaposed atrial appendages demonstrates unusual position of atrial septum (**white arrow**) and leftward placement of the right atrial appendage (RAA) behind the pulmonary artery (PA).

patient. They used venoatrial situs plus other clues of situs ambiguous (midline liver, indefinite stomach bubble, symmetric pulmonary vascular pattern, and interrupted or midline inferior vena cava) to define atrial situs. Angiography reliably predicted atrial visceral situs, ventricular morphology, and the relation of the great arteries.

Meyer et al[12] and Solinger et al[13] used M-mode echocardiography to assess noninvasively atrioventricular relationships and arrangement of the great vessels in 12 patients with dextrocardia. Using plain roentgenography of the chest to assess atrial situs as described by Van Mierop et al,[14] they were able to define some important anatomic relations before cardiac catheterization.

In our experience, 2-dimensional echocardiography is vastly superior to M-mode echocardiography in accurately determining the morphology and the position and connection of the cardiac chambers. Wide-angle 2-dimensional echocardiography significantly enhanced spatial orientation and the ability to integrate multiple tomographic sections of the heart during scans. Associated abnormalities such as ventricular septal defect and straddling AV valves can be reliably predicted. When 2 semilunar valves are present, the positions of the great arteries and the ventriculoarterial connection can be confidently defined.

In this study, we attempted to predict situs using findings available only to the echocardiographer. Combining information about the location of the liver and the location and drainage pattern of the inferior vena cava and hepatic veins, we were able to determine noninvasively the correct situs (as determined by cardiac catheterization and angiography) in this series of patients. We also utilized superior vena caval position and drainage, pulmonary venous drainage to the left atrium, and coronary sinus drainage to the right atrium (when identified) as secondary criteria for determination of atrial visceral situs. According to previous studies,[1] the use of venoatrial situs alone is reliable for identifying situs solitus and situs inversus, but is not specific for identifying situs ambiguous. Similarly, we found 2-dimensional echocardiography useful in accurately predicting situs solitus and situs inversus but nonspecific once situs ambiguous was determined. Further studies, including 2-dimensional echocardiographic examination of the pulmonary arterial anatomy with use of suprasternal notch scans and abdominal examination for the presence of a spleen, may be further predictive of bilateral right-sidedness (asplenia) versus bilateral left-sidedness (polysplenia). In addition, computed tomographic scans of the abdomen, as recently reported,[16] appear to be specific for these diagnoses, as are methods that use plain roentgenograms of the chest for determining the bronchial pattern. Presence of Howell-Jolly bodies on peripheral blood smear is also presumptive evidence of asplenia.

Our noninvasive findings agree with those resulting from other methods in previous studies with regard to AV connection in the subgroups of dextrocardia. With dextrocardia and atrial situs solitus, complex congenital heart disease is likely, with both AV discordance and univentricular heart being more common than AV concordance. With dextrocardia and atrial situs inversus, AV concordance is likely; in our series, only 1 patient had AV discordance and 3 had univentricular heart.

Left juxtaposed atrial appendages were present in 5 patients and were diagnosed by 2-dimensional echocardiography in 2. Others[9] have also noted the association between isolated dextrocardia and left juxtaposed atrial appendages.

Two-dimensional echocardiography was compared with angiography; the 2 methods were found comparable (and complementary) with respect to determination of ventricular morphology and definition of the relation of the great arteries. Angiography was superior to echocardiography in defining the ventriculoarterial connections in the presence of pulmonary valve atresia or near-atresia. Two-dimensional echocardiography was clearly superior to angiography in defining the AV valve anatomy and associated abnormalities such as AV valve straddling.

Two-dimensional echocardiography allows the accurate assessment of a number of complex congenital heart defects associated with dextrocardia. Utilizing a segmental approach, one can correctly predict atrial-visceral situs, ventricular morphology and situs, AV connections, and ventriculoarterial connections.

Conotruncal Malformations: Diagnosis in Infancy Using Subxiphoid 2-Dimensional Echocardiography

STEPHEN P. SANDERS, MD, FREDRICK Z. BIERMAN, MD, and ROBERTA G. WILLIAMS, MD

Subxiphoid 2-dimensional echocardiography was performed and interpreted before the first cardiac catheterization in 109 of 113 infants less than 1 year of age with conotruncal malformations, situs solitus of the atria, and d-ventricular loop. The 4 remaining infants could not be examined using this technique for technical reasons.

In 104 of 109 patients successfully examined a correct diagnosis was obtained with the use of subxiphoid 2-dimensional echocardiography. All patients with d-transposition of the great arteries had a correct diagnosis, and in 10 of 11 patients various types of double-outlet right ventricle were recognized by direct visualization of ventriculoarterial connection. Tetralogy of Fallot was correctly diagnosed in 34 of 36 patients and tetralogy of Fallot and pulmonary atresia were correctly diagnosed in 8 of 9 patients, on the basis of the position of the infundibular septum and presence or absence of continuity between the main pulmonary artery and the right ventricle. Five of 6 patients with truncus arteriosus communis were correctly diagnosed by demonstrating a connection between the pulmonary arteries and the ascending portion of the single large semilunar root. Subxiphoid 2-dimensional echocardiography proved to be a sensitive and specific technique for diagnosing conotruncal malformations in infancy.

Malformations of the conotruncus account for 25 to 30% of all congenital heart defects producing serious illness in the first year of life.[1] Included in this category are d-transposition of the great arteries, double-outlet right ventricle, tetralogy of Fallot, tetralogy of Fallot with pulmonary atresia, and truncus arteriosus communis. These lesions usually produce severe derangements of cirulatory physiology, often requiring early diagnosis and intervention to avoid serious morbidity and mortality.

These complex malformations involve 2 separate segments of the heart—the conotruncus and the ventricles. Subxiphoid 2-dimensional echocardiography permits simultaneous visualization of both segments in multiple planes of examination and should be especially useful in diagnosing conotruncal malformations. Since subxiphoid 2-dimensional echocardiography is most applicable in infancy, when patients with these lesions usually are seen, we studied prospectively the accuracy of this technique in diagnosing conotruncal malformations during the first year of life.

Methods

Study patients: From January 1978 through September 1980 subxiphoid 2-dimensional echocardiography was attempted before the first cardiac catheterization in 128 infants under 1 year of age with conotruncal malformations. Of these, 15 had atrial situs inversus or ambiguous or l-looped (inverted) ventricles and are not included in this report. The remaining 113 infants with situs solitus of the viscera and atria and d-ventricular loop (noninverted ventricles) are the subjects of this report. The ages of the 113 patients ranged from 1 day to 12 months (median 21 days) and their weights from 1.3 to 8.9 kg (median 3.4 kg).

Echocardiography: Subxiphoid 2-dimensional echocardiography was performed with the patients in a supine position, using a Picker Echoview 80 Cardiac Imager with mechanical sector scanner. A 5 MHz short-focused transducer with a 13 mm active element diameter was used for all examinations.[2] The sector arc varied between 45 and 60° with an image rate of 45 to 60/s and a variable line density. All examinations were displayed with inversion of the sector image[3] and were recorded on 0.5 inch videocassette tape. Stop-frame imaging allowed still photographs to be taken using a Tektronics C-50/C-70 series Landpack camera with Polaroid 084 film.

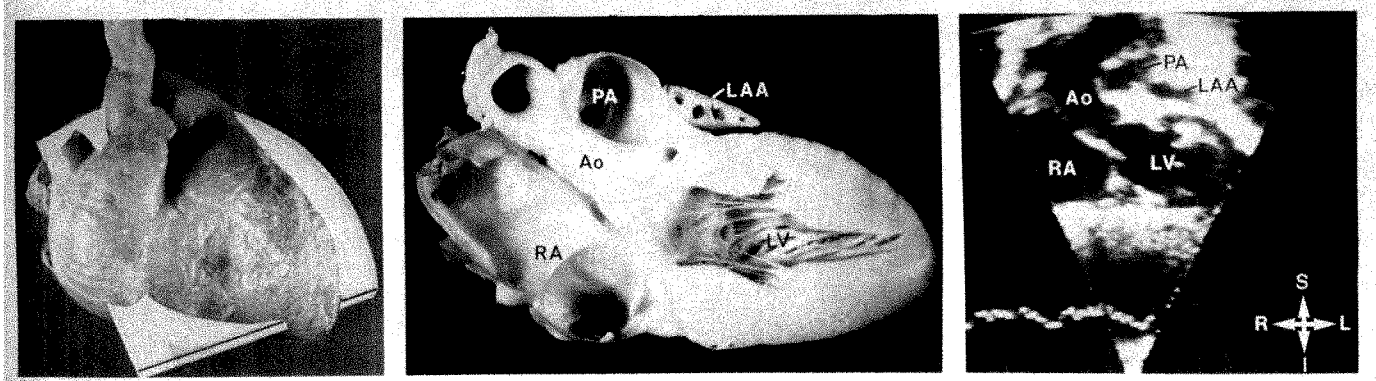

FIGURE 1. Long axis view of left ventricle. **Left,** plane in which the echo beam intersects the heart to generate this view. **Center,** anatomic section of normal heart model cut in this plane. **Right,** subxiphoid 2-dimensional echocardiogram of heart with normally related great arteries. Ao = aorta; I = inferior; L = left; LAA = left atrial appendage; LV = left ventricle; PA = pulmonary artery; R = right; RA = right atrium; S = superior.

Technique: Each echocardiographic examination was begun with the transducer on the subxiphoid area perpendicular to the coronal plane of the trunk. Cranial or anterior (approximately 50°) and leftward (10 to 15°) angulation of the transducer produced a long-axis view of the left ventricle and posterior semilunar root (Fig. 1). A coronal plane view of the right ventricle, right ventricular outflow tract, and anterior semilunar root was obtained with further (60 to 70°) anterior angulation (Fig. 2).

Clockwise rotation (90°) of the transducer about its long axis produced a transverse or cross-sectional view of the heart. While multiple transverse planes were examined,[2] 2 were particularly useful in diagnosing conotruncal malformations. Angling the transducer toward the left sternoclavicular joint displayed a transverse section of the base of the ventricles, the origin of the rightward semilunar root, and the membranous and atrioventricular canal portions of the interventricular septum (transverse plane A, Fig. 3). Additional angulation toward the medial third of the left clavicle displayed the left-sided semilunar root, the infundibular septum, and the mid-muscular septum (transverse plane B, Fig. 4).

Cardiac catheterization: Conotruncal anatomy was displayed using biplane cineangiography, including standard anteroposterior and lateral projections as well as various angled oblique views,[4] and was described using the nomenclature of van Praagh and co-workers.[5,6]

Data analysis: The echocardiography was performed and the results were interpreted by the echocardiographer before cardiac catheterization. The cineangiograms were reviewed and interpreted by the cardiovascular radiologist. Routine clinical data, including physical examination, chest x-ray, electrocardiogram, and arterial blood gases, were available to both. Cineangiographic diagnoses were accepted as correct for purposes of scoring the echocardiographic results.

Results

Subxiphoid 2-dimensional echocardiography was successfully performed as the primary diagnostic procedure in 109 of the 113 infants with conotruncal malformations associated with atrial situs solitus and d-ventricular loop (noninverted ventricle). In 4 patients, an adequate subxiphoid 2-dimensional echocardiographic examination could not be performed because of poor patient cooperation (2), recent abdominal surgery (1), and marked pulmonary hyperexpansion in 1 patient with absent pulmonary valve syndrome. The atrial situs and ventricular loop were correctly deter-

mined in all 109 patients. (Thirteen of the other 15 patients with conotruncal malformations associated with atrial situs inversus or ambiguous or l-ventricular loop [inverted ventricles] were also correctly identified prospectively using subxiphoid 2-dimensional echocardiography. The ventricular loop could not be determined echocardiographically or angiographically in the 2 remaining patients with single ventricular chamber.) The correct diagnosis was made in 104 (95%) of the 109 patients successfully examined using subxiphoid 2-dimensional echocardiography (Table I).

D-transposition of the great arteries (Fig. 5): All 46 patients with d-transposition of the great arteries were correctly identified prospectively on the basis of great artery morphology and direct visualization of ventriculoarterial connections.[3] There were no false-positive diagnoses.

An intact interventricular septum was correctly diagnosed in 19 of 20 patients and a ventricular septal defect was recognized in 16 of 23 patients (68%) by subxiphoid 2-dimensional echocardiography. Seven false-negative reports were issued in patients with trivial muscular (5) or membranous (1) ventricular septal defects which were hemodynamically insignificant and did not influence management. Three of 46 patients had tricuspid atresia with transposition of the great arteries; all were correctly diagnosed by echocardiography.

The only associated lesion which complicated the diagnosis of d-transposition of the great arteries was a malalignment ventricular septal defect (that is, a defect associated with anterior placement of the infun-

TABLE I Subxiphoid 2-Dimensional Echocardiographic Results by Diagnostic Category

	Angiography	Correctly Diagnosed by Echocardiography	Errors
Transposition of the great arteries	46	46	0
Double-outlet right ventricle	12	11	1

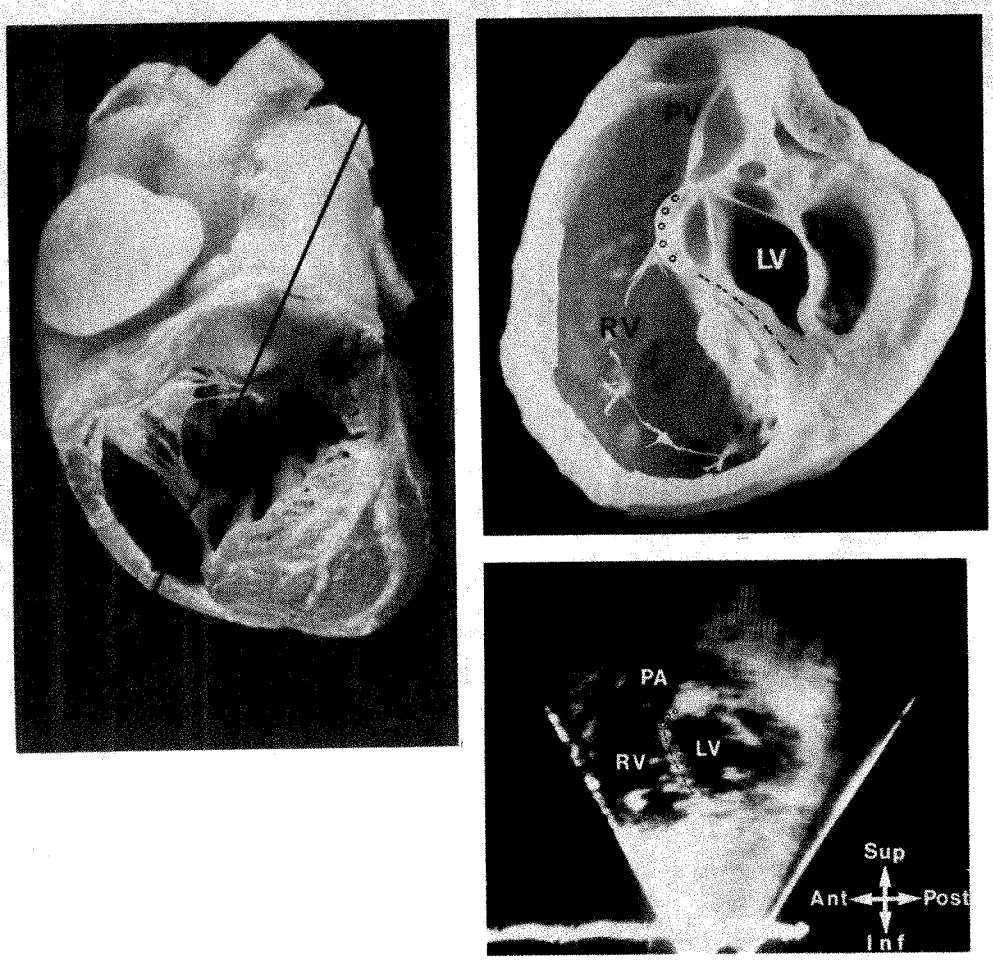

FIGURE 4. Transverse plane B, transverse plane through the left-sided semilunar root, the infundibular septum (**circles**) and the mid-muscular interventricular septum (**dashed line**). **Left,** plane in which the echo beam intersects the heart to generate this view. **Right,** anatomic section of normal heart model cut in this plane. **Bottom,** subxiphoid 2-dimensional echocardiogram of heart with normally related great arteries. Abbreviations as before.

dibular septum allowing the posterior semilunar root to override the interventricular septum[7]) in which the pulmonary artery straddled the interventricular septum symmetrically (2 of 5 patients with d-transposition of the great arteries and malalignment ventricular septal defect), making differentiation between d-transposition of the great arteries and double-outlet right ventricle difficult. Apparent continuity between the mitral and pulmonary valves as well as a difference in the heights of the semilunar valves (pulmonary inferior and aortic superior) suggested the diagnosis of d-transposition of the great arteries in both patients. One of these 2 patients died at the time of the intracardiac repair. Postmortem examination revealed a small (approximately 2 mm) strip of muscle (conus) between pulmonary and mitral valves. However, the relation between the pulmonary artery and the ventricles was ambiguous.

Double-outlet right ventricle (Fig. 6): This anomaly was correctly diagnosed in 11 of 12 patients on the basis of great artery position with respect to the interventricular septum. The origin of at least "1½" great arteries from the right ventricle, as demonstrated in the coronal plane of the right ventricle or transverse plane A or B, or both, was considered diagnostic of double-outlet right ventricle.[8–12] While the origins of side-by-side semilunar roots were well seen in the coronal plane view of the right ventricle, the identity of each root could best be determined using the transverse planes. The only patient with double-outlet right ventricle incorrectly diagnosed by subxiphoid 2-dimensional echocardiography had a small ascending aorta associated with severe coarctation and a large patent ductus arteriosus. The main pulmonary artery and ductus arteriosus (which were continuous with the descending aorta) were mistaken for the ascending and transverse aorta. The ascending aorta was small and not recognized. This led to the incorrect diagnosis of d-malposition of the great arteries with pulmonary atresia.

Double-outlet right ventricle was correctly characterized in 11 of 11 patients on the basis of the relative position of the great arteries, the degree of subsemilunar narrowing, the position of the ventricular septal defect, and the status of the mitral valve and left ventricle. In 6 patients the aorta was to the right and posterior with a subaortic ventricular septal defect (tetralogy of Fallot

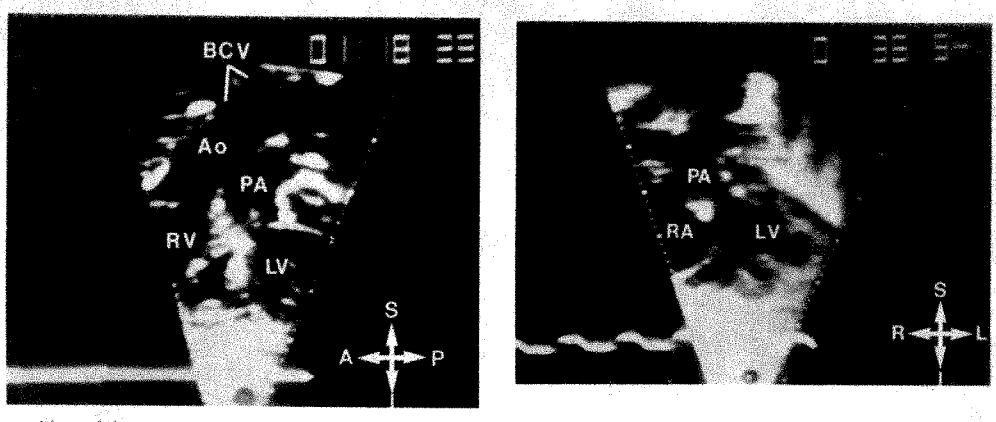

FIGURE 5. D-transposition of the great arteries. **Left,** long axis view of left ventricle. The posterior pulmonary artery (PA) is identified by bifurcation into branch pulmonary arteries. **Right,** transverse plane A. The arch-forming aorta (Ao) arises from the anterior right ventricle (RV). Superior border of the arch is broken by origins of the brachiocephalic vessels (BCV). P = posterior; other abbreviations as before.

type). Narrowing of the subpulmonary area was identified in 5 of the 6. The great arteries were relatively side by side with a rightward aorta in 3 patients; the ventricular septal defect was subpulmonary in 2 (Taussig-Bing type) and uncommitted in 1. The other 3 patients had double-outlet right ventricle associated with mitral atresia or severe mitral stenosis and hypoplasia of the left ventricle.

The relative positions of the great arteries were determined from the orientation of the transducer in a plane which displayed both great arteries simultaneously. Subsemilunar narrowing was assessed qualitatively from multiple sweeps of the outflow tracts in both transverse and coronal planes. The position of the ventricular septal defect relative to the great arteries was determined by identifying which great artery was closer to the defect in 1 of the transverse planes. If neither of the great arteries could be imaged in the same transverse plane as the ventricular septal defect, it was considered uncommitted. The status of the mitral valve and left ventricle was determined from multiple transverse and long axis views.

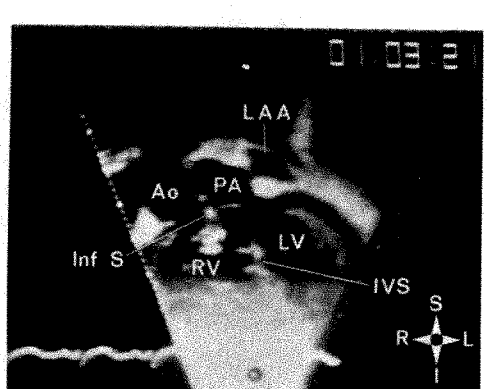

FIGURE 6. Coronal plane of right ventricle in case of double-outlet right ventricle. Both great arteries (Ao and PA) arise above the right ventricle (RV); the identity of the great arteries can not be determined in this view. IVS = interventricular septum; abbreviations as before.

Tetralogy of Fallot (Fig. 7): Thirty-four of 36 patients with tetralogy of Fallot were correctly diagnosed by subxiphoid 2-dimensional echocardiography. The criteria used were (1) anterior displacement of the infundibular septum associated with subpulmonary narrowing and a malalignment ventricular septal defect with overriding aortic root, and (2) a demonstrable pulmonary valve and continuity between the right ventricular outflow tract and the main pulmonary artery.[8–12] One patient, early in our experience, was incorrectly diagnosed as having a membranous ventricular septal defect without right ventricular outflow tract obstruction. The other patient misdiagnosed in this group was thought to have tetralogy of Fallot and pulmonary atresia after subxiphoid 2-dimensional echocardiography, whereas cineangiography showed a severely stenotic right ventricular outflow tract. Thus, in 35 of 36 patients with tetralogy of Fallot, a pulmonary valve and a patent right ventricular outflow tract could be demonstrated.

Tetralogy of Fallot and pulmonary atresia (Fig. 8): Eight of 9 patients with tetralogy of Fallot and pulmonary atresia were correctly diagnosed using subxiphoid 2-dimensional echocardiography by demonstrating (1) a large aortic root overriding the interventricular septum through a malalignment ventricular septal defect (with no demonstrable pulmonary valve and outflow tract), and (2) no direct connection between the pulmonary arteries and the ascending aorta. The diagnostic error in this category resulted from mistaking the left atrial appendage for the proximal main pulmonary artery, leading to the diagnosis of tetralogy of Fallot with a patent outflow tract.

Truncus arteriosus communis (Fig. 9): Truncus arteriosus communis was correctly diagnosed in 5 of 6 patients. The diagnostic criteria were (1) a single semilunar root overriding the interventricular septum through a malalignment ventricular septal defect, and (2) direct continuity between 1 or both pulmonary arteries and the ascending portion of the single semilunar root. In all 5 patients correctly diagnosed the truncal

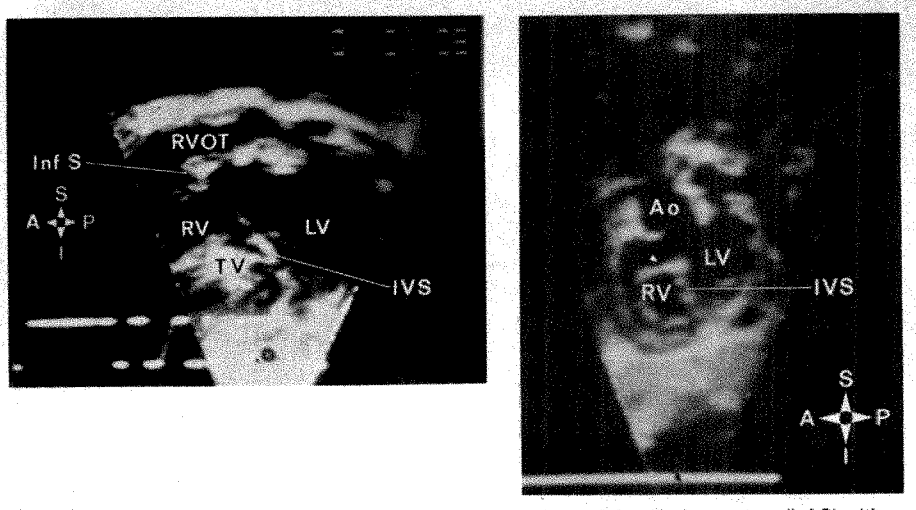

FIGURE 7. Tetralogy of Fallot. **Left,** transverse plane B showing the anteriorly displaced infundibular septum (Inf S) with narrowed right ventricular outflow tract (RVOT) and malalignment ventricular septal defect (IVS). **Right,** transverse plane A showing the dilated aorta (Ao) overriding the interventricular septum. The malalignment ventricular septal defect is below the aortic valve and above the superior septal attachments of the tricuspid valve (**white arrow**). A = anterior; other abbreviations as before.

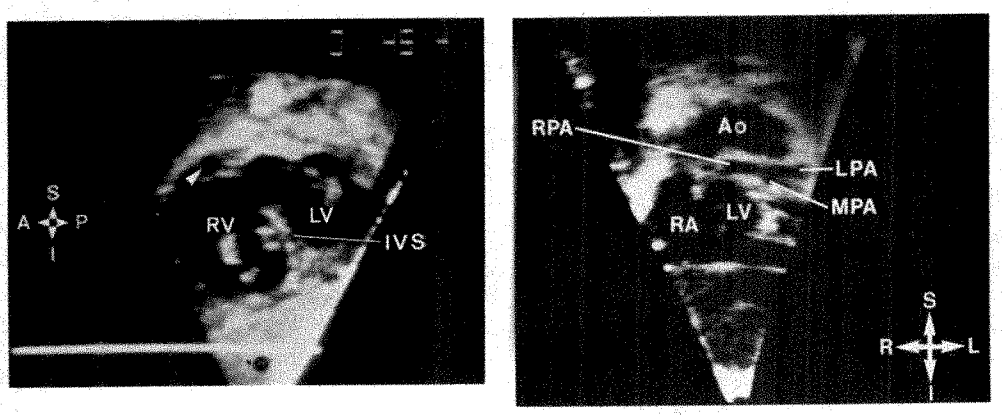

FIGURE 8. Tetralogy of Fallot with pulmonary atresia. **Left,** transverse plane B. The blindly ending right ventricle outflow tract (**white arrow**) is seen in this view. Continuity between the right ventricle (RV) and the pulmonary artery can not be demonstrated by scanning to either side of this plane. **Right,** caudal angulation from the long axis of the left ventricle (LV) displays confluence of the branch pulmonary arteries (RPA and LPA). The main pulmonary artery (MPA) ends proximally as a blind diverticulum (gull-wing appearance). Abbreviations as before.

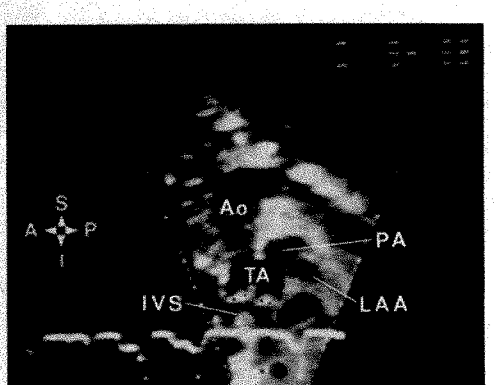

FIGURE 9. Transverse plane A in truncus arteriosus communis Type I-A. The truncal valve (**dotted line**) is large and thickened. The aortopulmonary septum is seen distally dividing the truncus (TA) into its aortic (Ao) and pulmonary artery (PA) portion. Abbreviations as before.

valve was large; in 4 it appeared thickened and dysplastic with an eccentric orifice. The sixth patient was incorrectly diagnosed as having double-outlet right ventricle after a limited examination. Poor visualization of the anterior portion of the right ventricle led to the false impression that a second outflow tract was present.

Discussion

Subxiphoid 2-dimensional echocardiography proved to be a sensitive and specific method for diagnosing conotruncal malformations. The only specific limitation to its use was an abnormality of the abdominal wall restricting transducer placement. We found that multiple plane imaging, facilitated by the broad acoustical window of the subxiphoid space, was extremely important in diagnosing these complex cardiac malformations.

Imaging in multiple coronal and transverse planes allowed a more precise description of the spatial orientation of the various structures.

Potential for diagnostic error: We believe that the ability to display the ventricles and the great arteries simultaneously is a further advantage of subxiphoid 2-dimensional echocardiography in diagnosing conotruncal malformations. The identity of each great artery can be determined on the basis of its morphologic features and its ventricular connections can be directly visualized. While a potential source of error peculiar to this approach is misidentification of a great artery (as in our case of double-outlet right ventricle incorrectly diagnosed), our experience suggests that careful attention to the morphologic criteria for great artery identification[3] should virtually eliminate this problem.

Since all structures are viewed in more than 1 plane, with less than 1 mm axial and less than 2 mm lateral resolution, difficulties resulting from false drop-out or superimposition of adjacent structures occurred rarely and led to diagnostic errors in only 2 patients; 1 patient had tetralogy of Fallot with pulmonary atresia and the other had truncas arteriosus communis.

Problems with resolution caused only 1 significant error in diagnosis. A single patient with tetralogy of Fallot was misdiagnosed as having tetralogy of Fallot with pulmonary atresia because the right ventricular outflow tract was not visualized with our equipment. Such narrowed anterior outflow tracts challenge the resolving power of even high frequency, wide active element diameter transducers with excellent axial and lateral resolution. Perhaps other methods such as Doppler echocardiography[13] will improve diagnostic accuracy in such situations.

Clinical applications: To determine the clinical utility of subxiphoid 2-dimensional echocardiography in the diagnosis of conotruncal malformations in infants we attempted to approximate the usual clinical setting in the design of the study. Thus, the echocardiographer was aware of the physical and laboratory findings while performing and interpreting the subxiphoid 2-dimensional echocardiographic examination. While a complete echocardiographic examination was performed in virtually all cases, the clinical information may have allowed the examiner to focus on areas of interest suggested by the clinical data.

Under the conditions of our study, subxiphoid 2-dimensional echocardiography, using multiple planes of examination, proved to have a diagnostic accuracy similar to that of contrast angiography. Although other types of conotruncal malformations (for example, l-transposition or other types of l-looped or inverted ventricles) were excluded for the sake of brevity and unity, inclusion of such lesions would have little effect on the results. Nonetheless, in our own practice subxiphoid 2-dimensional echocardiography has not replaced cardiac catheterization and angiography on a routine basis. Rather, the 2 methods are used in a complementary fashion: echocardiography is used to screen patients suspected of having congenital heart disease and to provide a general diagnosis; cardiac catheterization and angiography are then applied, as needed, to supply physiologic data and anatomic details not demonstrable with echocardiography.

The ability of 2-dimensional echocardiography to measure right ventricular (RV) volume and ejection fraction was assessed in 22 children with congenital heart disease. From the apical 4 chamber 2-dimensional echocardiographic image, the long-axis length of the right ventricle was measured and the area planimetered. On the anteroposterior and lateral cineangiocardiographic planes, the right ventricle was separated into 2 parts: RV sinus and outflow tract. The longest length, inflow tract length, and area of the sinus were measured from biplane cineangiographic views. The echographic long-axis length correlated well with the longest length of the RV sinus measured from both anteroposterior and lateral cineangiographic views at both end-systole and end-diastole. Moreover, the echographic area correlated well with the sinus area obtained from both cineangiographic views. From these regression analyses, the echographic long axis length and area were corrected to the angiographic longest length and area of the sinus. The new corrected echographic longest length and area were applied to 3 formulas (2 biplane and 1 uniplane) to calculate the sinus volume of the right ventricle. Total RV volume was then derived from the sinus volume. RV volumes and ejection fraction determined by 2-dimensional echocardiography were compared with those obtained from biplane cineangiography using Simpson's rule method. All formulas tested predicted RV volumes and ejection fraction with equal accuracy. Thus, 2-dimensional echocardiography can assess RV volume and ejection fraction in children with congenital heart disease.

RV dimension from M-mode echocardiographic images has been used to identify patients with RV volume overload[1-4] but cannot be used to determine RV volume. Recently, the 2-dimensional echocardiographic apical 4-chamber image has been employed to measure RV dimensions and area.[5,6] Bommer et al[5] showed that the RV area and minor axis length correlated well with the volume of RV casts. The use of computer analysis of 2-dimensional echocardiographic images has facilitated the noninvasive evaluation of left ventricular volumes and ejection fraction in adults[7-9] and children.[10,11] To date, however, determination of RV volumes by 2-dimensional echocardiography has been achieved only in adults with chronic obstructive lung disease[12] and in children with complete transposition of the great arteries after Mustard's procedure.[13] We have introduced a simplified angiographic area-length method for estimating RV volumes[14] (see Appendix). The present study was therefore undertaken to assess the accuracy of RV volume determination in infants and children with congenital heart disease by application of the new simplified area-length method to cross-sectional echocardiographic images.

Methods

Study patients: Twenty-two consecutive patients scheduled for diagnostic cardiac catheterization and 2-dimensional echocardiography were entered into the study. The clinical diagnoses are summarized in Table I. Ages ranged from 1

TABLE I Patient Data

Diagnosis	Patients (n)	Age Range (yr)
Normal heart	2	0.6, 8.0
Atrial septal defect	4	1.0–3.0
Atrial septal defect (postop)	1	0.9
Cardiomyopathy	1	0.8
LV-RA communication	1	4.0
Tetralogy of Fallot	2	3.0, 5.0
Total anomalous pulmonary venous return	2	0.8, 0.8
Transposition of great vessels (postop)	2	2.0, 3.0
Valvular pulmonary stenosis	2	5.0, 11.0
Ventricular septal defect	5	0.16–8.0

LV-RA = left ventricular-right atrial; postop = postoperatively.

month to 11 years (mean 2.9) and body surface area ranged from 0.18 to 1.3 m^2 (mean 0.52). All patients underwent 2-dimensional echocardiographic examination within 24 hours of cardiac catheterization.

Echocardiography: Echocardiographic studies were performed using a commercially available phased array sector scan (Toshiba SSH-10A). A transducer composed of 32 piezoelectric crystals (2.4 MHz) which were dynamically focused was employed. The echographic beam was steered electronically through a 78° sector arc. The focal point was adjusted to 4.5 or 7.5 cm depending on the size of the patient. Axial and lateral resolution was established by an ultra-Cal standard 100 mm test object phantom box. Axial resolution was 1 mm at any depth and lateral resolution was 1.5 to 2 mm at and before the focal point. At 2 cm from the focal point, lateral resolution became 2.5 mm, and at 5 cm from the focal point, it became 3 mm.

The apical 4-chamber image was obtained with the head of the patient slightly elevated and the patient in a 45° left lateral decubitus position. The transducer was applied to the apex and the sector fan directed to the right shoulder.[15] Care was taken to record a clear endocardial image by optimizing gain settings. The images were recorded on videotape at 30 frames/s (Nipon Electric, Tokyo, Japan) for later playback and analysis in the stop-motion mode. From the apical 4-chamber 2-dimensional echographic view, the long-axis length and area of the right ventricle were measured at end-systole and end-diastole (Fig. 1). The long-axis length was measured from the apex to the center of the tricuspid valve. The area of the right ventricle was traced on transparent onlay paper from the endocardial surface of the right ventricle through the plane of the tricuspid valve. When small defects in the endocardial echoes were observed, the area of outline was completed by a straight line between adjacent clear endocardial echoes. The area was then calculated by means of a graphic image analyzer (Neumonics, Philadelphia, Pennsylvania) interfaced with a minicomputer (Wang, Tewksbury, Massachusetts).

An attempt was made to determine the timing of end-systole and end-diastole for echocardiographic measurements. In 14 patients in whom tricuspid valve motion was clearly defined on the apical 4-chamber image, the long-axis length and area of the right ventricle were obtained by using closure and opening of the tricuspid valve as end-diastole and end-systole, respectively. These measurements were also obtained by using the onset of the QRS complex of the reference electrocardiogram as end-diastole and the end of the T wave as end-systole.

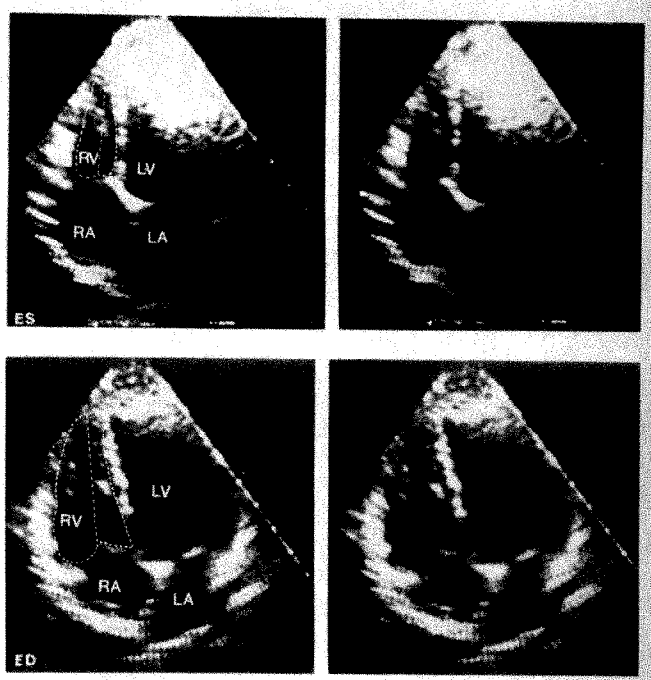

FIGURE 1. Two-dimensional echocardiogram in the apical 4-chamber view. **Top,** at end-systole (ES); **bottom,** end-diastole (ED). From this view the area (**dotted line** along the endocardial surface) of the right ventricle (RV) was planimetered and length (**dotted line** from apex to tricuspid valve) measured. LA = left atrium; LV = left ventricle; RA = right atrium.

Angiocardiography: Biplane cineangiocardiography was performed in the anteroposterior and lateral projection at 60 frames/s after injecting 1.0 to 1.25 ml/kg of body weight of 76% Renografin® into the right atrium or the right ventricle. The patient was always in the supine and horizontal position. Only sinus beats were used to measure RV dimensions and volumes. The right ventricle was separated into 2 parts, the RV sinus and outflow tract, by constructing a horizontal line on both cineangiographic views[16] (Fig. 2). RV end-diastolic and end-systolic volumes were calculated using the Simpson's rule method.[17] *Right ventricular ejection fraction (RVEF) was calculated by the equation:* RVEF = (RVEDV − RVESV)/RVEDV, where RVEDV is right ventricular end-diastolic volume and RVESV is right ventricular end-systolic volume.

The following measurements were also obtained from biplane cineangiographic images of the right ventricle at end-diastole and end-systole: (1) RV inflow length = the distance from the apex of the right ventricle to the mid-tricuspid valve; (2) the longest length of the RV sinus = the longest distance from the apex to any portion of the tricuspid valve; and (3) the RV sinus area.

Corrected echocardiographic measurements: The RV length and area measurements obtained from 2-dimensional echocardiography were compared with the variables obtained from both anteroposterior and lateral cineangiographic views. From these regression equations, we derived the corrected echographic longest length of the right ventricle. In a similar fashion, the corrected echographic area was also derived. These corrected values were then used to calculate RV sinus volume. Total RV volume was calculated from the sinus volume of the right ventricle in 20 patients without tetralogy of Fallot by the following equations: *Method I* = TRVV = 1.061 × $(CEA_{AP} \times CEA_{LAT})/CELL_{AP}$; *Method II* = TRVV = 0.849

TABLE II Timing of End-Systole and End-Diastole

	End-Systole					End-Diastole				
	At End of T wave		At Opening of TV			At Onset of QRS Wave		At Closing of TV		
Variable	Mean	SD	Mean	SD	P	Mean	SD	Mean	SD	P
Length (cm)	3.3	0.94	3.1	0.97	0.1	4.5	1.3	4.4	1.3	0.1
Area (cm^2)	4.7	2.6	4.5	2.4	0.1	8.3	3.5	8.4	3.7	0.1

SD = standard deviation; TV = tricuspid valve.

$\times (CEA_{AP} \times CEA_{LAT})/CELL_{LAT}$; and *Method III* = TRVV $= 1.316 \times (CEA_{LAT})^2/CELL_{LAT}$, where TRVV = total RV volume, CEA = corrected echographic area, CELL = corrected echographic long-axis length, AP = anteroposterior cineangiogram, and LAT = lateral cineangiogram. In the 2 patients with tetralogy of Fallot, total volume was obtained by using the constants 0.981, 0.785, and 1.217 for Methods I, II, and III, respectively.

Statistics: Linear regression analysis was performed using the least-squares method. The standard error of the estimate was calculated using the standard deviation. The difference beween the regression equation for the 3 methods was determined by testing the variance, slope, and Y intercept using analysis of covariance.[18] Student's *t* test was used to test the difference between the means in heart rate and timing of end-systole and end-diastole. The difference was statistically significant when the p value was less than 0.05.

Results

The heart rate during angiography (121.8 ± 28 beats/min, mean ± standard deviation) and 2-dimensional echocardiography (113.7 ± 33 beats/min) was not statistically different.

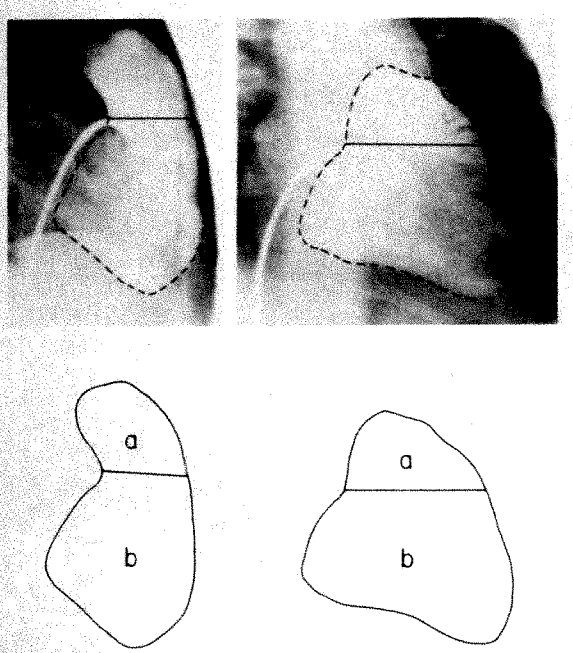

FIGURE 2. Lateral (**left**) and anteroposterior (**right**) cineangiocardiograms of the right ventricle. The **solid line** divides the right ventricle into RV outflow (a) and RV sinus (b).

Timing of end-systole and end-diastole: There was no significant difference in end-diastolic or end-systolic area and length when these measurements were obtained using either the electrocardiogram or tricuspid valve motion to establish timing of the cardiac cycle (Table II). Furthermore, the fractional percentage of long-axis length (end-diastolic length minus end-systolic length divided by end-diastolic length) was not significantly different when values were compared using either method. Therefore, in this study we used the electrocardiogram as a reference to determine end-systolic and end-diastolic frames.

Echographic versus angiocardiographic measurements: All echographic and angiographic dimensions and area measurements were of the RV sinus. The relation between the echographic long-axis length and area to the angiographic inflow-tract length, longest length, and area measured from the biplane cineangiographic views is summarized in Table III. A good correlation existed between all paired measurements. Echographic long-axis length underestimated the longest length measured from both angiographic views at end-diastole and end-systole. The echographic long-axis length underestimated the RV inflow length measured from the anteroposterior angiographic view at both end-systole and end-diastole and slightly overestimated the angiographic inflow tract dimension in the lateral view. The echographic RV area consistently underes-

TABLE III Linear Regression Equation Between Angiographic (y) and Echocardiographic (x) Variables of the Right Ventricular Sinus

Variable (y)	Slope	Intercept	r
1. RV inflow tract length (AP)			
End-diastole	1.72	−2.19	0.82
End-systole	1.92	−2.07	0.80

End-diastole	2.94	−5.65	0.86
End-systole	3.03	−3.45	0.79
Area of RVS (LAT)			
End-diastole	1.57	−0.32	0.92
End-systole	1.64	−0.82	0.85

AP = anteroposterior angiogram; LAT = lateral angiogram; RVS = right ventricular sinus.

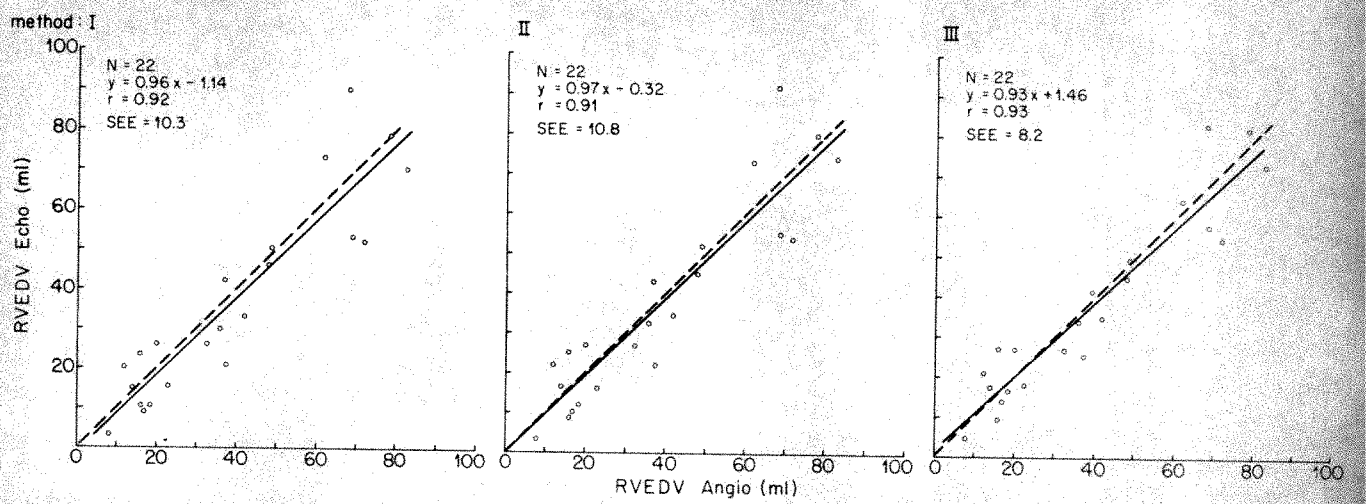

FIGURE 3. Correlation between RV end-diastolic volume calculated by echocardiography (echo) (**ordinate**) and measured by angiography (angio) (**abscissa**) for each method. r = correlation coefficient; SEE = standard error of the estimate; **dashed line** = the line of identity; **solid line** = regression line.

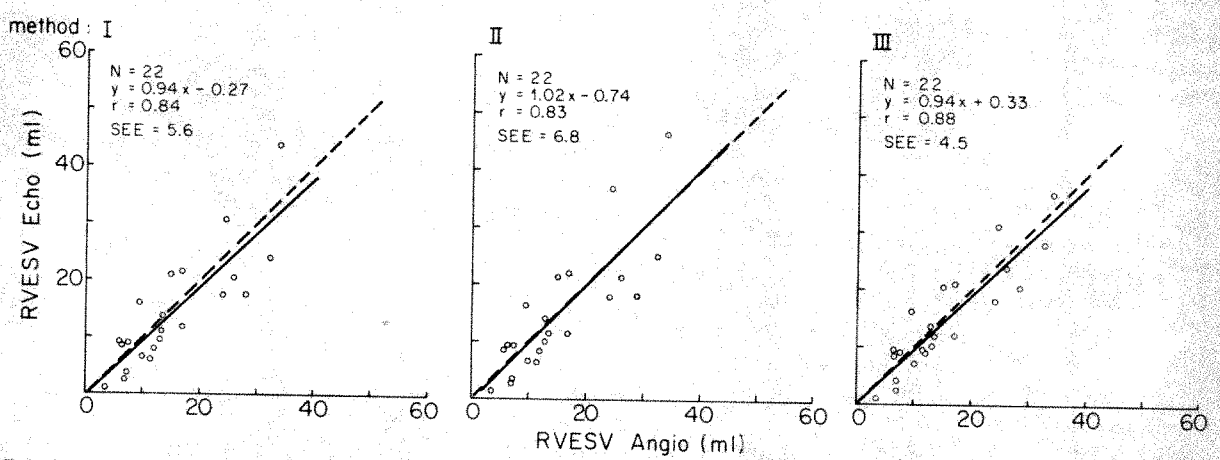

FIGURE 4. Correlation between RV end-systolic volume calculated by echocardiography (echo) and measured at angiography (angio) for each method. Format as in Figure 3.

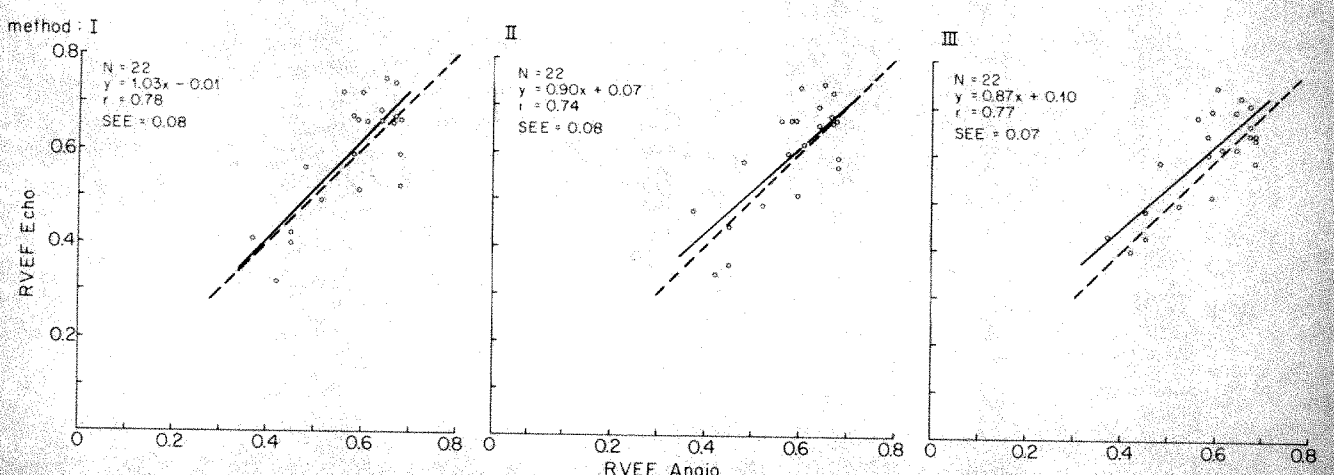

FIGURE 5. Correlation between RV ejection fraction calculated from echographic (echo) assessed volumes and calculated from angiographic (angio) volumes for each method. Format as in Figure 3.

timated areas obtained from both angiographic views. All echocardiographic measurements correlated better with lateral angiographic measurements than with anteroposterior measurements.

RV volume and ejection fraction determinations: All methods accurately estimated RV end-diastolic volume (Fig. 3). End-systolic volume correlated less favorably with angiographically determined volume (Fig. 4). The trend continued with RV ejection fraction (Fig. 5). There was no statistically significant difference between volume or ejection fraction determinations by either method.

Discussion

Two-dimensional echocardiographic imaging of the heart and great vessels has enhanced appreciably the clinician's scope of cardiac examination.[19] Various cross-sections of the right ventricle can now be visualized. Recently, 2 paired biplane methods were employed for echographic RV volume determination. Apical and subxiphoid views have been used in adults[12] and short-axis and apical views in children.[13] In the former study, however, the right ventricle was adequately viewed using these 2 planes in only 56% of adult patients. Furthermore, adequate visualization of the RV outflow tract is difficult even in children.[20] Apparently, determination of RV volume from 2-dimensional echocardiography should use the image of the RV sinus. Bommer et al[5] used the apical echographic image for measurement of RV dimensions and area and validated these variables by comparing measurements of echoed casts with actual cast data.

Validity of RV volume calculation from 2-dimensional echocardiography: To establish this validity, we compared echocardiographically determined area and length measurements from the apical 4-chamber view with angiocardiographic data. The echographic long-axis length correlated well with the angiographic RV inflow-tract length and the longest length of the RV sinus measured from either biplane cineangiographic views. However, the echographic length slightly overestimated the lateral inflow tract length and significantly underestimated all other angiographic dimensions. These results imply that the cross-section obtained from the apical 4-chamber echographic view is more comparable to the left anterior oblique angiocardiographic view, which is in agreement with Bommer's data[5] that the apical image is a right posterior oblique cross-section. The echographic area also correlated well with the angiographically determined area but routinely underestimated the angiographic area. The reasons for echographic underestimation of angiographic dimensions and area are (1) the echographic plane of sector is not identical to either angiographic plane, and (2) the echocardiogram excludes RV trabeculation. These findings indicate that the echographic area and long-axis dimension should be corrected before proceeding with volume determinations.

We have shown that total RV volume can be calculated from RV sinus volume in patients with various forms of congenital heart disease[14] (see Appendix). In the present study, therefore, total RV volume was calculated from 2-dimensional echocardiographic volume estimation of RV sinus from the apical 4-chamber image using 3 area-length formulas. It is not surprising that RV volume determined from a single echographic view predicted well angiographically determined volumes regardless of the hemodynamic derangement present. Our angiographic data obtained from 84 patients demonstrate that hemodynamic status does not affect the use of an area-length method for calculating RV volumes[14] (Appendix).

Accuracy of ejection fraction determination: Two-dimensional echocardiography best predicted end-diastolic volume. A weaker correlation existed when echographically determined end-systolic volume was compared with angiographically derived end-systolic volume. This weaker correlation may be explained by (1) spatial movement of the heart producing an altered plane of sector; (2) greater relative error in measuring a smaller end-systolic area; and (3) an error in frame selection for measuring end-systolic area and length. Indeed, the definition of end-systole by echocardiography is difficult.[21,22] In the present study, however, we demonstrated that there was no difference in echographic measurement using either tricuspid valve motion or the electrocardiogram for timing the events in the cardiac cycle. Thus, the timing of end-systole may not be a major factor. Furthermore, all the foregoing factors appeared to play a small role, because the correlation coefficient and standard error of the estimate for end-systole were good.

RV ejection fraction correlated the weakest when compared with angiocardiographically determined values. These data reflect a magnification of errors made in end-diastolic and end-systolic volume determination. In our echocardiographic methodology, biplane area-length formulas appeared of equal utility. The standard error of the estimate of end-diastolic volume and end-systolic volume was somewhat lower using the lateral uniplane method. This difference can be explained by the fact that the longest length and area of the right ventricle obtained echocardiographically correlated better with the longest length and area measured from the lateral angiographic view than from the anteroposterior view. Estimation of ejection fraction by area-length method I successfully differentiated all 4 patients with an ejection fraction less than 45%. Methods II and III identified only 3 of these 4 patients and an operative procedure did not significantly influence the predictive value of echocardiography for volume and ejection fraction calculation. Thus, further evaluation may be necessary to determine the accuracy of ejection fraction estimation with each method. It is notable that this study included 3 postoperative patients.

Limitations: Our method appears to have 2 built-in limitations: endocardial dropout and parallex distortion produced by the monitor screen. In addition, it appears tedious and time-consuming. We believe that application of direct computer analysis of the echographic image will facilitate RV volume analysis. Such image

analysis capability is commercially available in the form of a light pen microprocessor or sonic digitizer interfaced with a minicomputer.

Conclusions: These data indicate the following observations in pediatric patients with congenital heart disease: (1) The long-axis length of the right ventricle measured from the apical 4 chamber echographic view correlates well with both angiocardiographically measured RV inflow-tract length and the longest length of the RV sinus. Moreover, RV echographic area tracked the area of the sinus planimetered from angiocardiographic images. The degree of correlation was better for lateral angiocardiographic images than for anteroposterior images. (2) Two-dimensional echocardiography can accurately predict RV volumes. (3) Echographic estimation of ejection fraction was adequate but not as precise as volume determination.

Appendix

We performed a preliminary study to evaluate the feasibility of RV volume determination using 4 simplified area-length methods that would provide a basis for estimation of the RV volume by 2-dimensional echocardiography.[14] In this study, 84 unoperated patients were divided into 6 groups according to their hemodynamic status: normal right and left ventricular size (group 1, n = 16), RV volume overload (group 2, n = 17), RV pressure overload (group 3, n = 13), left ventricular volume overload (group 4, n = 12), left and RV volume overload (group 5, n = 12), and tetralogy of Fallot (group 6, n = 14). The RV cineangiocardiograms were separated into RV sinus and right ventricular outflow tract by drawing a horizontal line at the superior aspect of the tricuspid valve anulus (Fig. 2). Total RV volume and sinus volume were calculated by Simpson's rule. The ratio of sinus volume to total RV volume averaged 0.75 at both end-diastole and end-systole in all patients except those with tetralogy of Fallot. In the latter patients the ratio was 0.81. *The volumes of the RV sinus were calculated by the following 4 area-length methods: Biplane area-length method 1:* $SV = 0.8488\ (A_{AP} \times A_{LAT})/LL_{AP}$; *Biplane area-length method 2:* $SV = 0.8488\ (A_{AP} \times A_{LAT})/LL_{LAT}$; *Lateral uniplane area-length method:* $SV = 0.8488\ (A_{LAT}^2)/LL_{LAT}$; *Anteroposterior uniplane area-length method:* $SV = 0.8488\ [(A_{AP})^2]/LL_{AP}$, where SV = sinus volume, A = area, LL = longest length of the right ventricular sinus, AP = anteroposterior cineangiogram, and LAT = lateral cineangiogram.

Total RV volume was calculated by multiplying sinus volume by 1.23 in patients with tetralogy of Fallot and 1.33 in all other patients. Both biplane methods and the lateral uniplane method predicted accurately the total RV volume. However, biplane method 1 overestimated and the lateral uniplane method underestimated Simpson's rule RV volumes

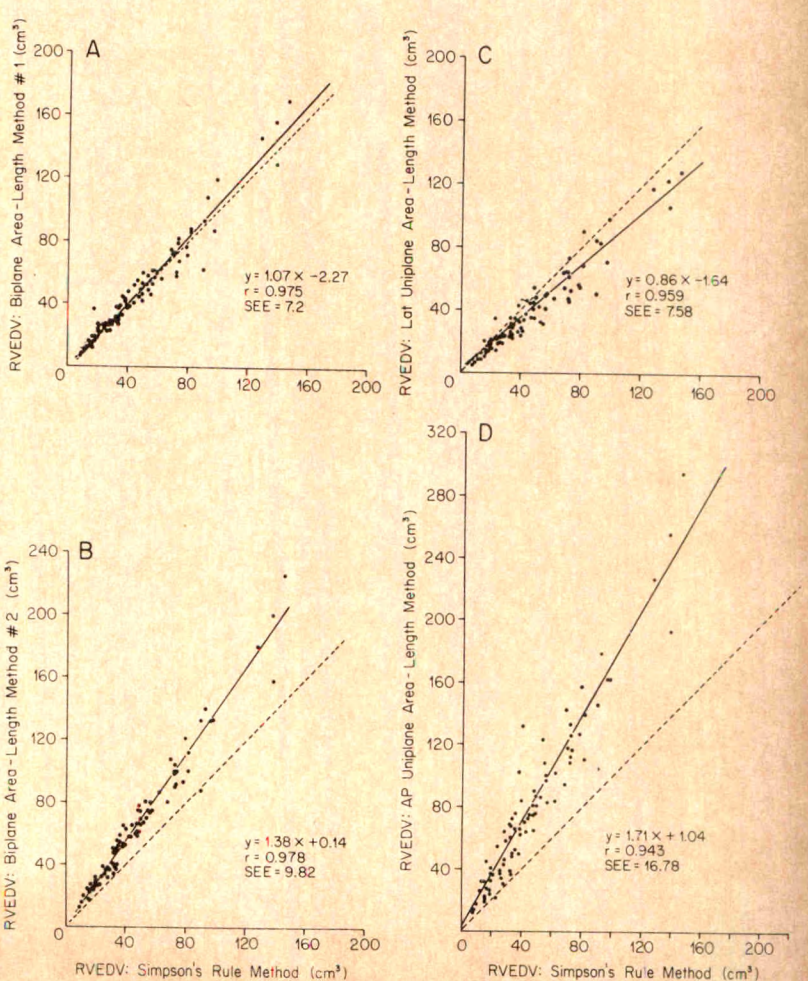

FIGURE 6. RV end-diastolic volume calculated by the 4 area-length methods as a function of RV end-diastolic volume calculated by Simpson's rule method. AP = anteroposterior.

(Fig. 6 and 7). The slope of the regression line was therefore used to correct for the degree of over- or underestimation. Thus, the following area-length formulas for calculating RV volume in patients without tetralogy of Fallot were obtained: *Biplane method 1:* $V = 1.061 \times (A_{AP} \times A_{LAT})/LL_{AP}$; *Biplane method 2:* $V = 0.849 \times (A_{AP} \times A_{LAT})/LL_{LAT}$; *Lateral uniplane method:* $V = 1.316 \times [(A_{LAT})^2]/LL_{LAT}$.

For children with tetralogy of Fallot, the constants were 0.981, 0.785, and 1.217 for biplane methods 1 and 2 and the lateral uniplane method, respectively. Moreover, RV ejection fraction was accurately predicted by these 3 methods (Fig. 8). These data indicate that these simplified methods are accurate for RV volume determination, irrespective of the patient's hemodynamic derangement.

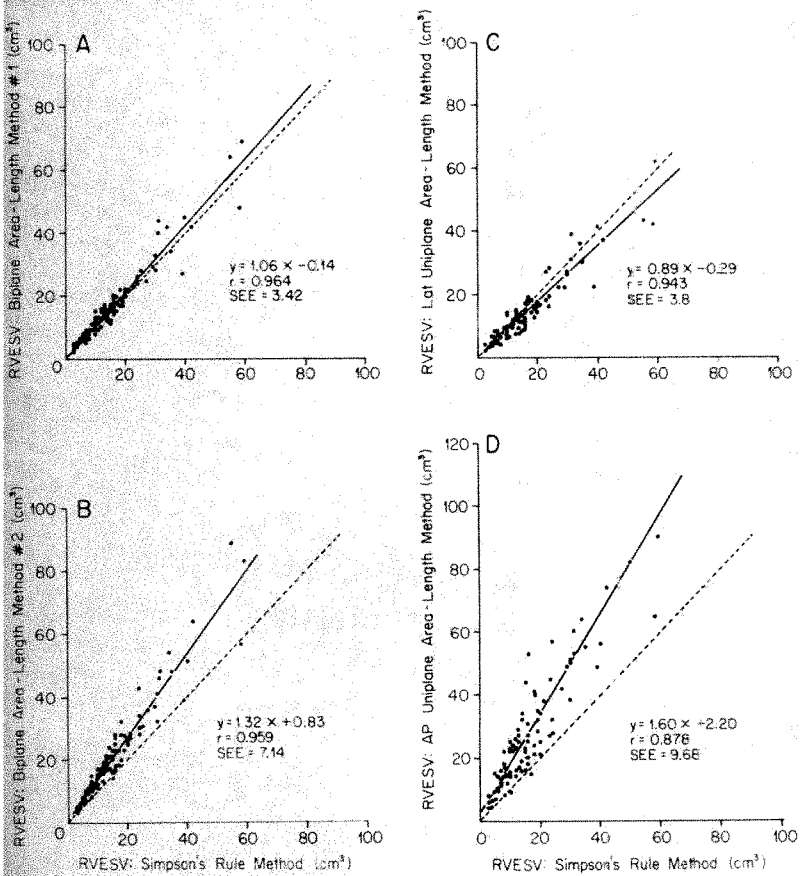

FIGURE 7. RV end-systolic volume calculated by the 4 area-length methods as a function of right ventricular end-systolic volume calculated by Simpson's rule method. LAT = lateral. Format as in Figure 6.

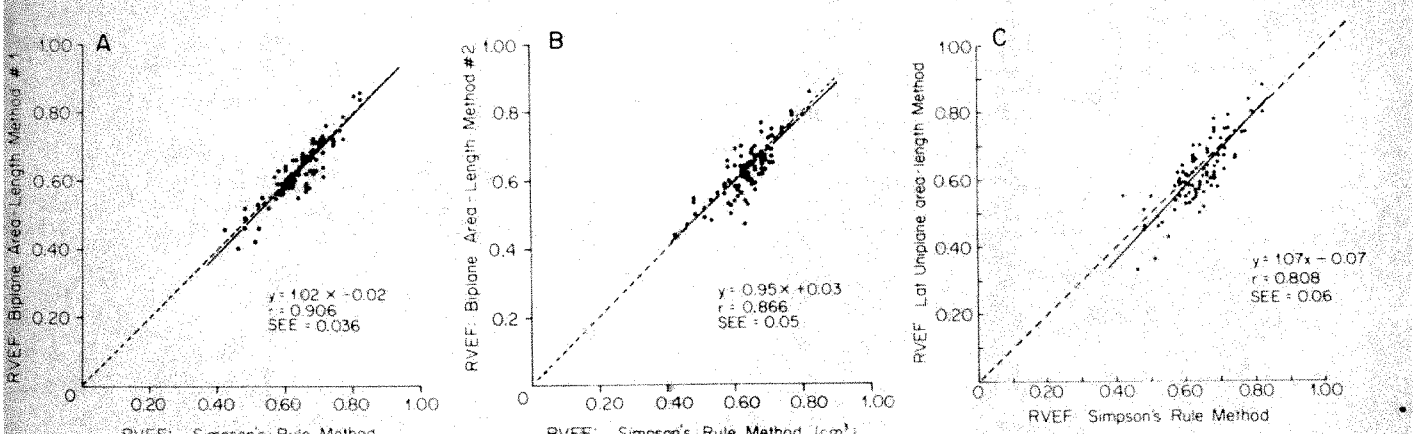

FIGURE 8. RV ejection fraction calculated by the 2 biplane area-length methods and lateral (Lat) uniplane method as a function of RV ejection fraction calculated by Simpson's rule method.

Two-Dimensional Echocardiographic Evaluation of Persistent Truncus Arteriosus

JOSÉ MARÍN-GARCÍA, MD and INA L. D. TONKIN, MD

Using a phased-array, wide angle sector-scanner, 2-dimensional echocardiograms were obtained in 3 patients with persistent truncus arteriosus. Type I was found in 2 patients and type II in 1 patient. In the patient with type II truncal valve stenosis was also present. Using a combination of short-axis views at the cardiac base, with 30° superior transducer angulation and parasternal long-axis views, the truncus arteriosus and the pattern of pulmonary arteries were demonstrated in each case.

M-mode echocardiographic diagnosis of persistent truncus arteriosus is based on the presence of a large arterial trunk overriding the interventricular septum and the inability to image the pulmonary valve.[1] Truncal valve thickening and an enlarged left atrium may also be present. However, these features do not differentiate this anomaly from tetralogy of Fallot or from pulmonary valve atresia and ventricular septal defect. Two-dimensional echocardiography provides a method to evaluate the relation between the truncus and the interventricular septum as well as to determine the presence or absence of right ventricular outflow. Previously, identification of the origin of the pulmonary arteries from the truncus arteriosus had been possible utilizing either a subcostal,[2,3] suprasternal,[4] or long-axis view.[5] In this report we describe the 2-dimensional echocardiographic features in 3 infants studied in our institution. Using a combination of short-axis views at the cardiac base with 30° superior transducer angulation and parasternal long-axis scans, the origin of the pulmonary arteries from the truncal root was clearly identified in each case. Truncus arteriosus type I was found in 2 infants and type II in 1. The diagnosis was confirmed by cineangiocardiography and subsequently at operation in each case.

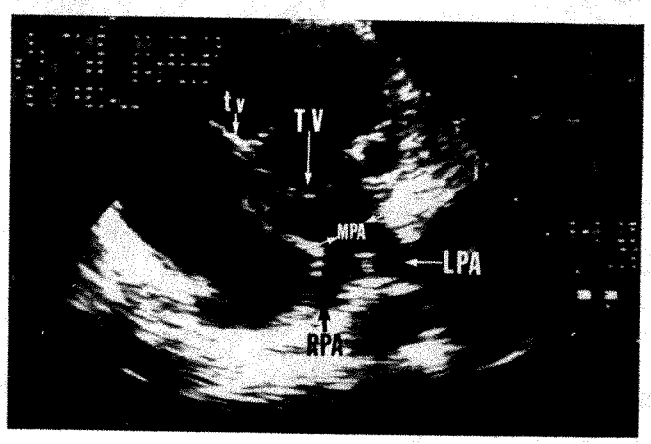
Methods

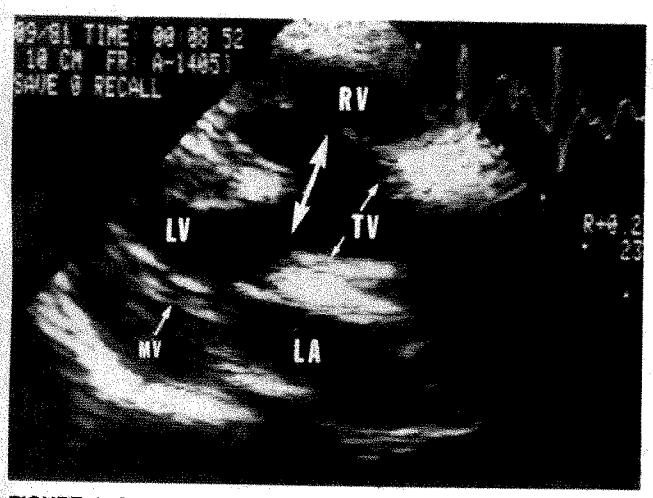
Three infants, aged 1 year, 4 weeks, and 7 months, respectively, underwent 2-dimensional echocardiographic study using a Varian V-3400R Associates 80° phased-array sector-scanner with a 3.5 MHz transducer. The image was displayed on a video monitor and recorded in real time on 0.5 inch video cassette tape. Still-frame pictures of the videotaped images were obtained for presentation. Each patient was examined in the supine and left lateral positions. Long- and short-axis, apical and subcostal 4-chamber, and subcostal long-axis scans were recorded as previously described.[6] Cross-sectional views through the truncus and pulmonary arteries using short-axis scans at the cardiac base with 30° superior transducer angulation were obtained in Cases 1 and 3, and scanning in an intermediate position between the parasternal long- and short-axis planes in Case 2.

Case Reports

Case 1. A 1 year old white girl was first seen at 8 days of age because of cyanosis and tachypnea. A 2-dimensional echocardiogram in the short-axis view showed a large truncal valve and anulus. A discrete main pulmonary artery was identified as originating from the truncus and shortly bifurcated in the right and left pulmonary arteries (Fig. 1, top). In the long-axis view a dilated great artery overriding the interventricular septum was well imaged (Fig. 1, bottom left). The diagnosis of truncus arteriosus type I was confirmed by cineangiocardiography (Fig. 1, bottom right) and subsequently at operation. The patient had a satisfactory postoperative course and is well 2 months after the operation.

Case 2. A 7 month old infant was referred with a history of respiratory distress since the newborn period. A 2-dimensional echocardiogram revealed a large arterial trunk overriding the interventricular septum in the long-axis view. Combining parasternal long- and short-axis scans, a single, large semilunar valve was imaged and with 30° superior angulation of the transducer; a main pulmonary artery was outlined, origi-





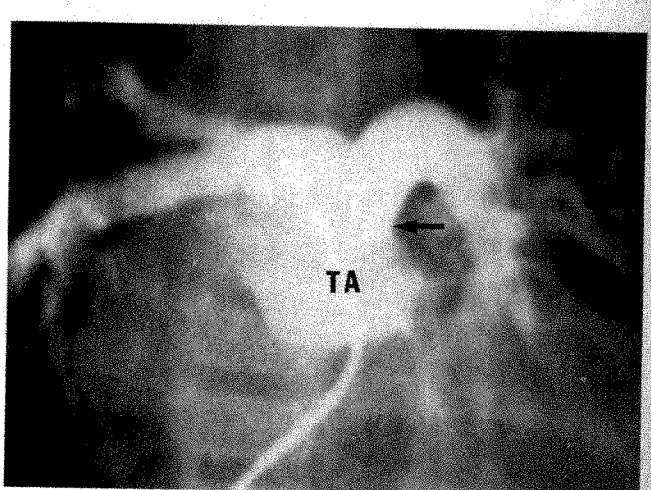


FIGURE 1. Case 1. **Top,** a 2-dimensional echocardiogram in the short axis view demonstrates persistent truncus arteriosus, type I. The truncal valve (TV) as well as the main pulmonary artery (MPA) is seen branching into the left (LPA) and right (RPA) pulmonary arteries. In addition, in this view the tricuspid valve (tv) is visualized. **Bottom left,** a 2-dimensional echocardiogram in the long axis shows a typical subtruncal ventricular septal defect (**large arrows**) and overriding of the interventricular septum by the truncal valve (TV). In this view the right ventricle (RV), left ventricle (LV), left atrium (LA), and mitral valve (MV) are also seen. **Bottom right,** contrast injection into the persistent truncus arteriosus (TA) shows a type I anomaly with a short main pulmonary artery (**arrow**) which branches into the right and left pulmonary arteries.

nating from the persistent truncus arteriosus and shortly bifurcating into the right and left branches (Fig. 2, top). Truncus arteriosus type I was confirmed by angled cineangiocardiography (Fig. 2, bottom) and subsequently at surgery. After a complicated course, the patient died in the early postoperative period.

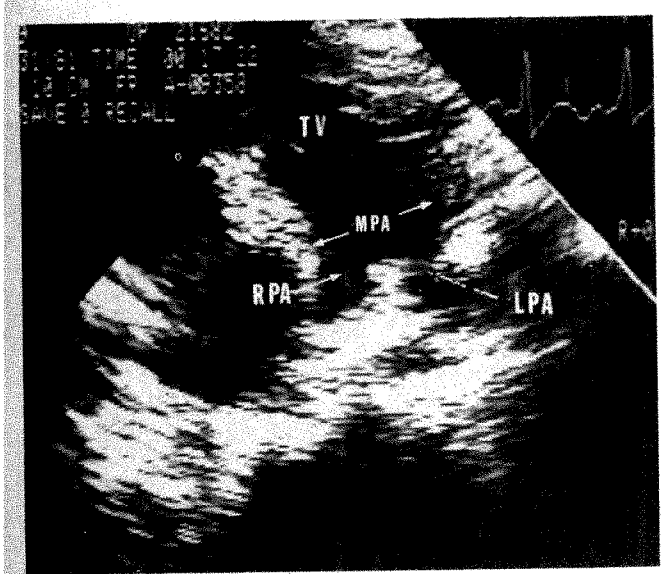
Case 3. A 6-week old infant was referred because of signs of increasing respiratory distress. A 2-dimensional echocardiogram in the short-axis view showed a dilated truncal anulus. Thick cusps were imaged and the right and left pulmonary arteries were seen originating separately from the truncus (Fig. 3, top). In the long-axis view a dilated great artery was demonstrated overriding the interventricular septum. Also in this view the semilunar cusps appeared thick and exhibited decreased motion. Angled cineangiocardiography demonstrated truncus arteriosus type II, with the right and left pulmonary arteries branching directly from the truncus (Fig. 3, bottom). Increased thickness and decreased motion of the valve with a dome configuration were also seen. At operation the diagnosis was confirmed and successful repair was accomplished.

Discussion

First reported by Buchanan[7] in 1864, persistent truncus arteriosus was classified by Collet and Edwards[8] into 4 types. In type I a discrete main pulmonary artery of variable length arises from the truncus arteriosus before bifurcating into the right and left pulmonary arteries. In type II and III there is no main pulmonary artery, and the right and left pulmonary arteries originate separately from either the lateral or the dorsal wall of the truncus. These cases are indistinctively referred to as type II. Much controversy remains as to whether type IV is truly a type of persistent truncus arteriosus or a single aortic trunk with agenesis of the sixth aortic arch.[9] Our cases are examples of type I and II.

In this study 2-dimensional echocardiography was an important method in differentiating persistent truncus arteriosus from other conotruncal anomalies in which the systemic artery overrides the interventricular septum, as in pulmonary valve atresia with ventricular

septal defect and tetralogy of Fallot. A combination of parasternal long- and short-axis scans allowed differentiation between these anomalies in each instance. Demonstration of the absence of the pulmonary valve and evaluation of the right ventricular outflow tract was possible by scanning in the short axis. In this view and with 30° superior transducer angulation, the origin of the pulmonary arteries from the truncal root was clearly demonstrated in Cases 1 and 3. Truncus arteriosus, type II, was identified in Case 3 and confirmed subsequently at cineangiocardiography and operation. In Case 2, the truncus arteriosus and pulmonary arteries were identified using an intermediate scan between parasternal long- and short-axis views with superior tranducer angulation. This finding suggests that some individual variation is possible and the echocardiographer must have this in mind when evaluating patients with truncus arteriosus.



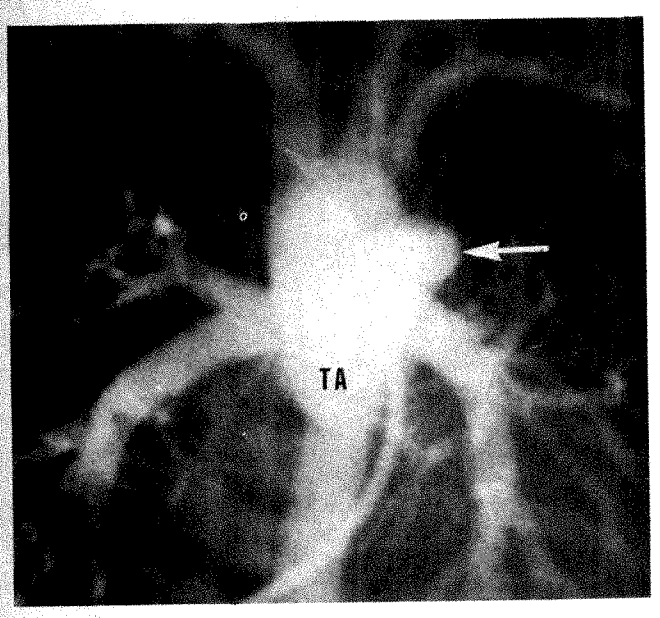


FIGURE 2. Case 2. **Top, A**, a 2-dimensional echocardiogram recorded in an intermediate position between a long- and short-axis shows the persistent truncus arteriosus and truncal valve (TV). There is a discrete main pulmonary artery (MPA) with early branching of the left (LPA) and right pulmonary arteries (RPA). **Bottom,** anteroposterior cineangiocardiogram confirms a type I persistent truncus arteriosus (TA). The main pulmonary artery (**white arrow**) and branches are clearly imaged.

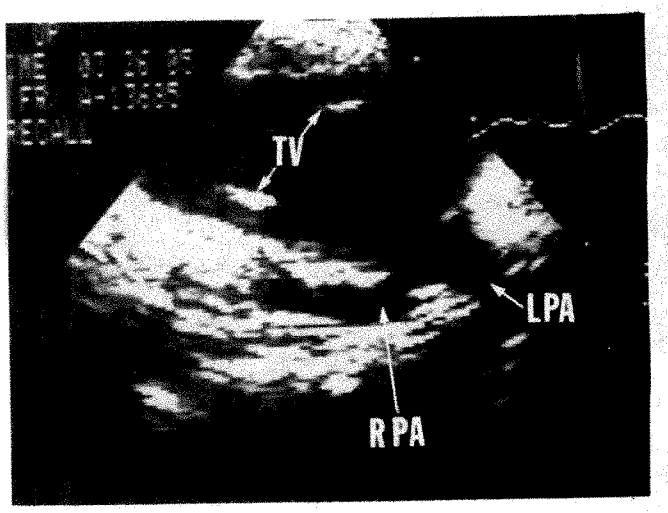

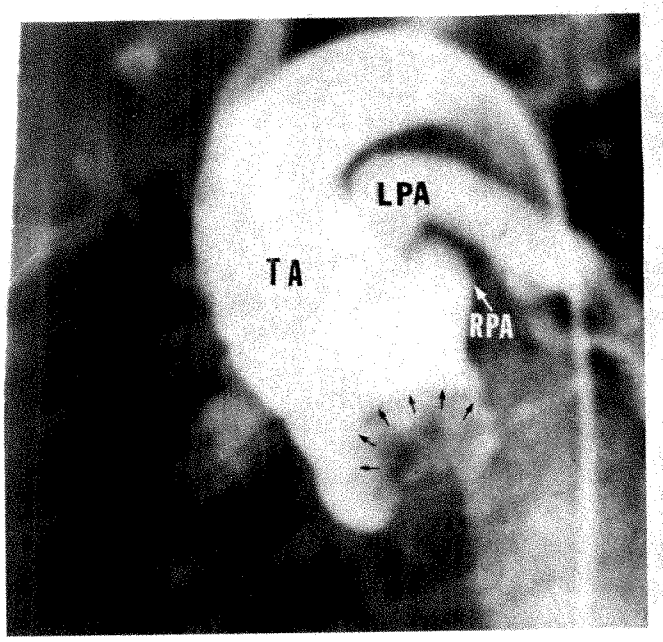

FIGURE 3. Case 3. **Top,** a 2-dimensional echocardiogram in the short axis view shows a thickened, echo-dense truncal valve (TV) and dilatation of truncal valve anulus. In addition, separate origin of the left (LPA) and right pulmonary arteries (RPA) from the truncus arteriosus is seen. **Bottom,** the 4-chamber or hepatoclavicular cineangiocardiogram demonstrates a large left-sided truncus arteriosus (TA) with separate origin of the left (LPA) and right pulmonary arteries (RPA). In addition, the truncal valve is domed (**arrows**) and stenotic.

Two-Dimensional Echocardiographic Prospective Diagnosis Of Common Truncus Arteriosus in Infants

THOMAS W. RIGGS, MD and MILTON H. PAUL, MD,
With the technical assistance of SUE PAJCIC

Two-dimensional echocardiographic prospective diagnosis of truncus arteriosus was made in 7 infants. Two infants had truncus arteriosus type I, 3 patients had truncus arteriosus type II, 1 infant had truncal valve stenosis with an interrupted aortic arch, and 1 had type IV truncus arteriosus with pulmonary hypertension. Multiple imaging views were utilized to confirm the diagnosis. The parasternal long-axis view demonstrated the great vessel-ventricular septal override and the origin of the pulmonary arteries from the posterior aspect of the ascending truncus. The suprasternal notch image facilitated identification of the left- or right-sided aortic arch and the origin of the pulmonary arteries from the truncus. Transverse imaging sections at the base of the heart facilitated identification of the pulmonary artery origin of truncus arteriosus type I. Subcostal coronal and sagittal views imaged the common truncus and the ventricular septal defect.

These echocardiographic images were contrasted with and discriminated from those of an infant with aorticopulmonary window with intact ventricular septum. Although cardiac catheterization and angiography may be required to assess pulmonary arterial pressure, pulmonary vascular resistance, and the distal pulmonary arterial anatomy in truncus arteriosus, 2-dimensional echocardiography can be used to correctly establish the morphologic diagnosis of truncus arteriosus in infants.

Two-dimensional echocardiography has greatly enhanced the clinician's ability to recognize and differentiate various conotruncal abnormalities with the common feature of systemic arterial-ventricular septal override. The spatial relation of the great arteries, their concordance to the ventricular chambers, and hypoplasia or atresia of the pulmonary valve can each be assessed.[1–4] The diagnosis of truncus arteriosus is established with demonstration of (1) a solitary great artery emerging from the ventricular chambers (almost invariably associated with a ventricular septal defect), and (2) the origination of both the aorta and the pulmonary artery (or arteries) from this great artery. Further subclassification depends on where the pulmonary artery (or arteries) originate from the truncus and whether the aortic arch is interrupted.[5,6]

From the Willis J. Potts Children's Heart Center, Division of Cardiology, Children's Memorial Hospital, and the Department of Pediatrics, Northwestern University Medical School, Chicago, Illinois. This study was supported in part by the Walden W. Shaw Foundation and the Feldstein Family Fund, Chicago, Illinois. Manuscript received March 22, 1982; revised manuscript received May 10, 1982, accepted June 9, 1982.

Address for reprints: Thomas W. Riggs, MD, Division of Cardiology, Children's Memorial Hospital, 2300 Children's Plaza, Chicago, Illinois 60614.

We report herein observations on 7 consecutively encountered infants in whom the prospective diagnosis of truncus arteriosus was made by 2-dimensional echocardiography and subsequently confirmed by angiography and surgery. The purpose of this report is to characterize the distinctive 2-dimensional echocardiographic features of truncus arteriosus, especially with regard to the origin of the pulmonary arteries, and to compare and contrast these echocardiographic observations with those from an infant with aorticopulmonary window with an intact ventricular septum.

Methods and Patients (Table I)

All patients had 2-dimensional echocardiographic examinations utilizing an Advanced Technology Laboratory 2-dimensional sector scanner with a 5.0 MHz transducer. Most of the images were obtained in standard echocardiographic planes and displayed according to accepted standards.[7] Minor angular or positional variations from standard imaging positions are elaborated under Results.

All patients except Case 8 underwent cardiac catheterization and angiography. This infant with an aorticopulmonary window had multiple congenital anomalies; the diagnosis was confirmed at autopsy. Two infants (Cases 1 and 6) were considered to have DiGeorge's syndrome.

TABLE 1 Clinical Summary

	Echocardiography		Cardiac Catheterization				Surgery			
Patient	Diagnosis	AO Arch	Age (yr)	Weight (kg)	Diagnosis	AO Arch	Age (yr)	Weight (kg)	Procedure	Findings
1	TRN I	R	0.10	2.5	TRN II	R	0.15	2.6	PAB	TRN II
2	TRN I	L	0.10	3.7	TRN I	L	0.17	3.8	Repair	TRN I
3	TRN I	L	0.01	3.0	TRN II	L	0.04	3.0	PAB	TRN II

AO = aortic; A-P = aorticopulmonary; IAA = interrupted aortic arch; L = left; LPA = left pulmonary artery; PAB = pulmonary arterial banding; R = right; RPA = right pulmonary artery; TRN = truncus arteriosus; TS = truncal stenosis.

Results

Parasternal long-axis view: This view allowed visualization of the size and extent of the ventricular septal defect as well as the systemic arterial override in all patients except Case 8. The specific diagnosis of truncus arteriosus was suspected by the appearance of a defect in the posterior wall of the truncus, establishing communication between the truncus and the pulmonary arteries (Fig. 1). Frequently this could be appreciated by placement of the transducer in a high parasternal position (second or third left interspace) with slight rotation of the imaging plane in a clockwise or counterclockwise direction, allowing optimal imaging of the communication between the truncus and the pulmonary artery.

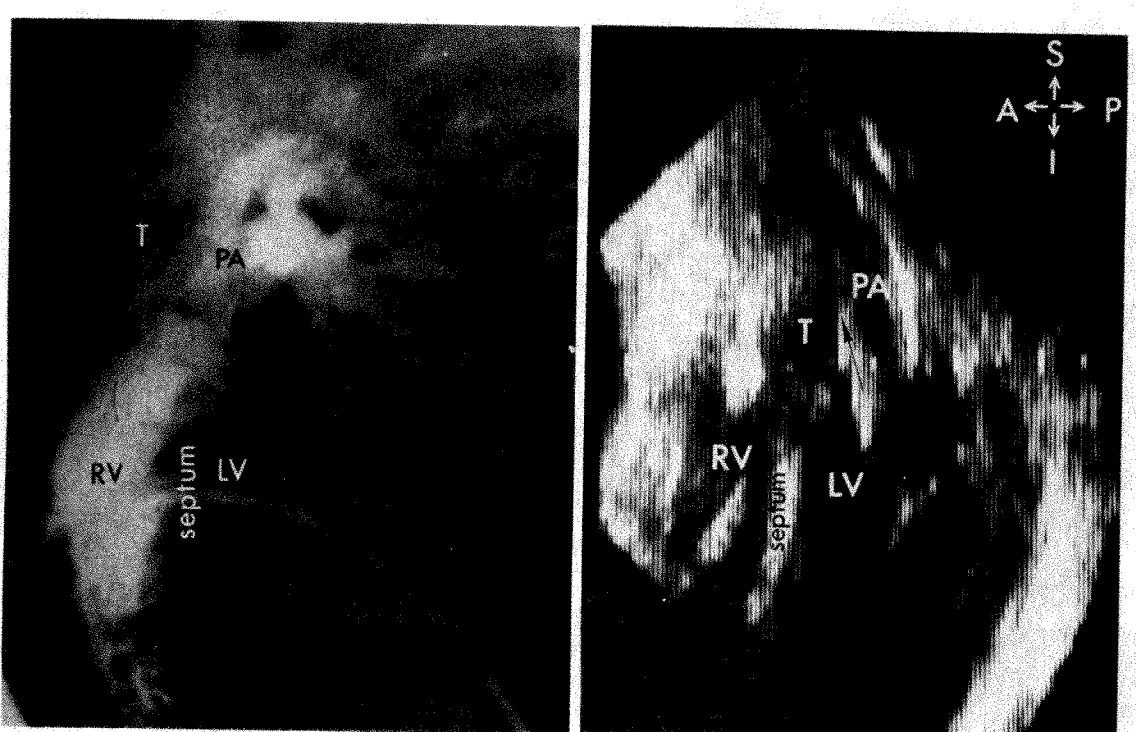

FIGURE 1. Left, angiocardiogram (Case 2) represents a right ventricular injection with opacification of the truncus arteriosus, pulmonary arteries, ascending aorta, and subsequently (through a ventricular septal defect) the left ventricle. The echocardiographic, angiographic, and surgical diagnosis was truncus, type I. **Right,** parasternal long-axis view (Case 2) demonstrates the overriding truncus arteriosus, ventricular septal defect, and the communication (**arrow**) between the truncus and the pulmonary artery. The echo image axis is realigned to correspond to the normal angiographic orientation. A = anterior; I = inferior; LV = left ventricle; P = posterior; PA = pulmonary artery; RV = right ventricle; Septum = interventricular septum; S = superior; T = common truncus arteriosus.

Parasternal transverse (short-axis) view: Successive transverse sections beginning at the cardiac base and moving superiorly to image the great arteries emerging from the heart were useful in confirming the diagnosis of truncus arteriosus (Fig. 2). The usual septation of the aorta from the pulmonary artery was incomplete, and in this view a communication between the aorta and pulmonary arteries was visualized in the 5 patients with type I or type II truncus arteriosus. In all 5 cases, an echocardiographic diagnosis of type I truncus arteriosus was suggested because a short segment of main pulmonary artery was visualized. In 3 of these cases, however, the angiographic and surgical diagnosis was type II, implying closely adjacent right and left pulmonary arteries without an intervening main pulmonary artery segment. In the infant with truncus arteriosus and interrupted aortic arch, this short-axis view clearly imaged the communication between a small ascending aorta and a very large main pulmonary artery; however, this view did not provide satisfactory visualization of the aorticopulmonary window in our solitary case.

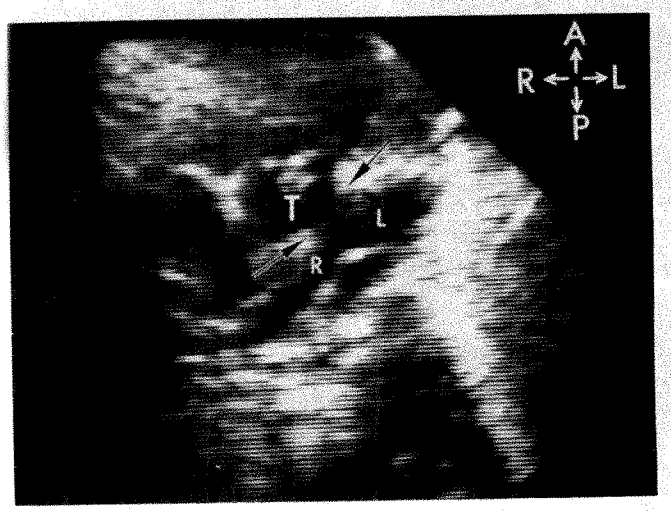

FIGURE 2. Transverse short-axis view of the truncus arteriosus (Case 2) and its communication with the pulmonary arteries (**arrows**) in a patient with type I truncus. A = anterior; L = left pulmonary artery; P = posterior; R = right pulmonary artery; T = truncus arteriosus.

Subcostal views: The subcostal approach in a coronal plane visualized the ventricular septal defect and the overriding great vessel (Fig. 3). However, the demonstration of the truncal origin of the pulmonary arteries was not possible in this plane, since the pulmonary arteries were posterior to the plane of the ventricular septal defect and ascending truncus. With angulation of the transducer into a sagittal plane, the ascending truncus, aortic arch, and descending aorta could be visualized along their long axis. In this plane, the origin of the pulmonary arteries from the posterior aspect of the ascending truncus could be demonstrated in patients with type I or II (Fig. 4). The subcostal approach imaged the intact ventricular septum in our patient with an aorticopulmonary window.

Suprasternal notch view: Using this view, the situs of the aortic arch was correctly identified as right in 3 patients, left in 4 patients, and interrupted in the remaining case. In the infant with truncus arteriosus type IV, the right pulmonary artery was identified as originating from the descending aorta. Moderate proximal right pulmonary arterial stenosis was present on 2-dimensional echocardiography (Fig. 5, left) and was

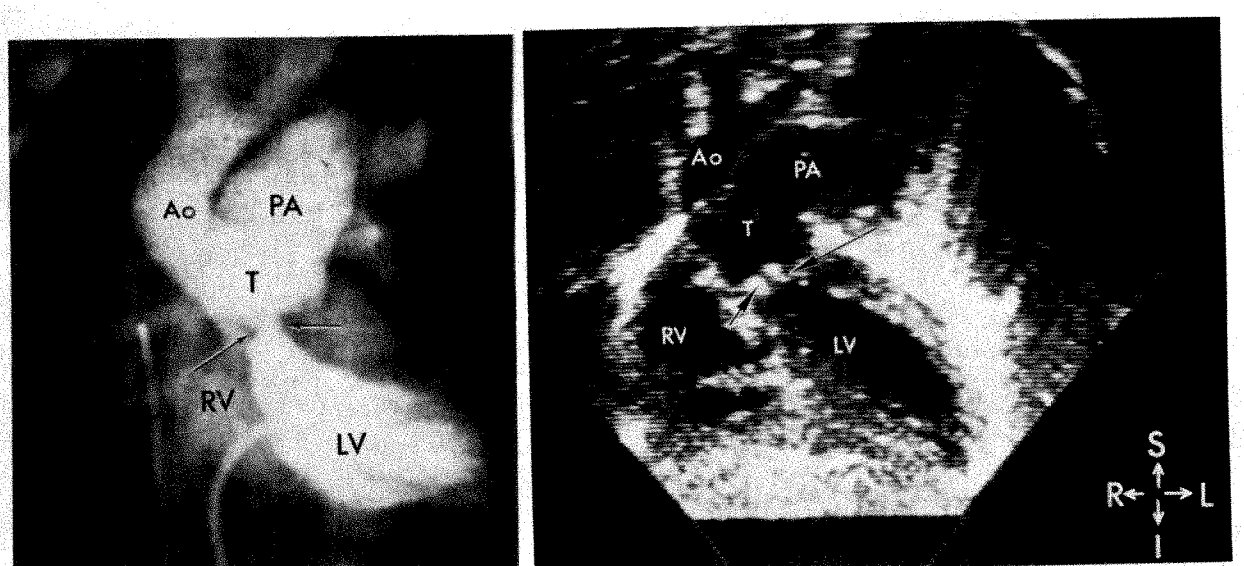

FIGURE 3. Left, angiocardiogram (Case 7) representing a left ventricular injection. The stenotic truncal valve is highlighted with **arrows** and the common truncus (T) gives rise to an interrupted aortic arch and a large pulmonary artery. The ventricular septal defect is not well visualized in this frame, although the right ventricle is opacified. **Right,** subcostal long-axis left ventricular echocardiogram obtained in coronal plane (Case 7) and inverted to correspond with angiocardiogram alignment in Figure 3A. The truncal stenosis (**arrow**) is clearly demonstrated; the ventricular septal defect and the truncus arteriosus with interrupted aortic arch are also imaged. Abbreviations as before.

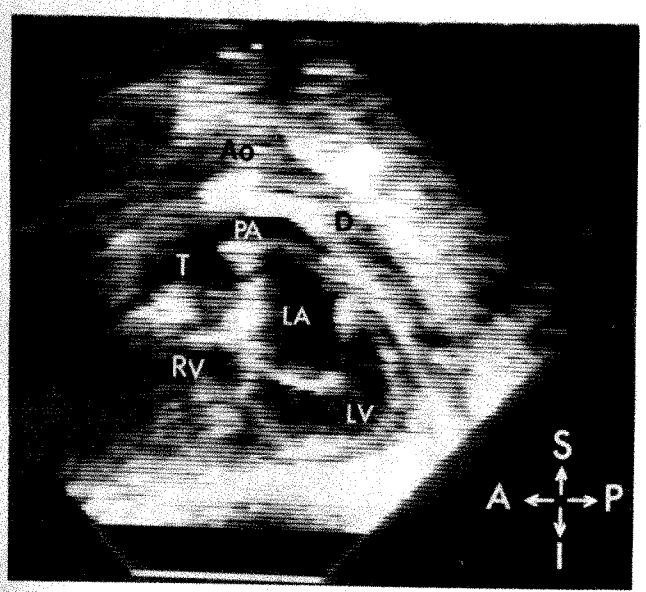

FIGURE 4. Subcostal echocardiogram, obtained in a sagittal plane (Case 3) and inverted to conventional head-foot axis, visualizes the truncus arteriosus, pulmonary artery, and descending aorta. In this plane, the ventricular septal defect is not imaged, but the origin of the pulmonary artery from the truncus is clear. D = descending aorta; LA = left atrium; other abbreviations as before.

confirmed anatomically at cardiac angiography (Fig. 5, right) and by pressure data. The left pulmonary artery could not be imaged on the echocardiogram but was seen on angiography and at surgery to originate more distally from the descending aorta. The suprasternal notch view imaged the aorticopulmonary window present in Case 8 (Fig. 6).

Discussion

Two-dimensional echocardiography can provide reliable identification and classification of conotruncal abnormalities. Although previous studies have described some of the echocardiographic findings in patients with truncus arteriosus,[1–3,8] our study, based on the prospective echocardiographic diagnosis of truncus arteriosus in 7 infants, extends those observations using multiple imaging planes.

The parasternal long-axis view demonstrates the systemic arterial override and the ventricular septal defect in patients with truncus arteriosus. This nonspecific finding also occurs in tetralogy of Fallot, pulmonary atresia with a ventricular septal defect, isolated large subaortic ventricular septal defect, double outlet right ventricle, and, occasionally, in complete transposition of the great arteries with a ventricular septal defect. The specific diagnosis of truncus arteriosus may be considered if in this view a communication can be demonstrated between the pulmonary artery and the truncus arteriosus.

Short-axis scans at the base of the heart identify hypoplasia of the right ventricular outflow tract in tetralogy of Fallot and ventricular-arterial discordance in transposition of the great arteries. Thus, tetralogy of Fallot, transposition of the great arteries, and double outlet right ventricle can be differentiated both from normal and from each other.[1,8] Careful scanning at the base of the heart facilitates the diagnosis of truncus arteriosus, since the solitary semilunar valve and origin of the pulmonary arteries from the truncus can be visualized.

Subcostal views are particularly useful in small infants since in a single view, extensive intracardiac

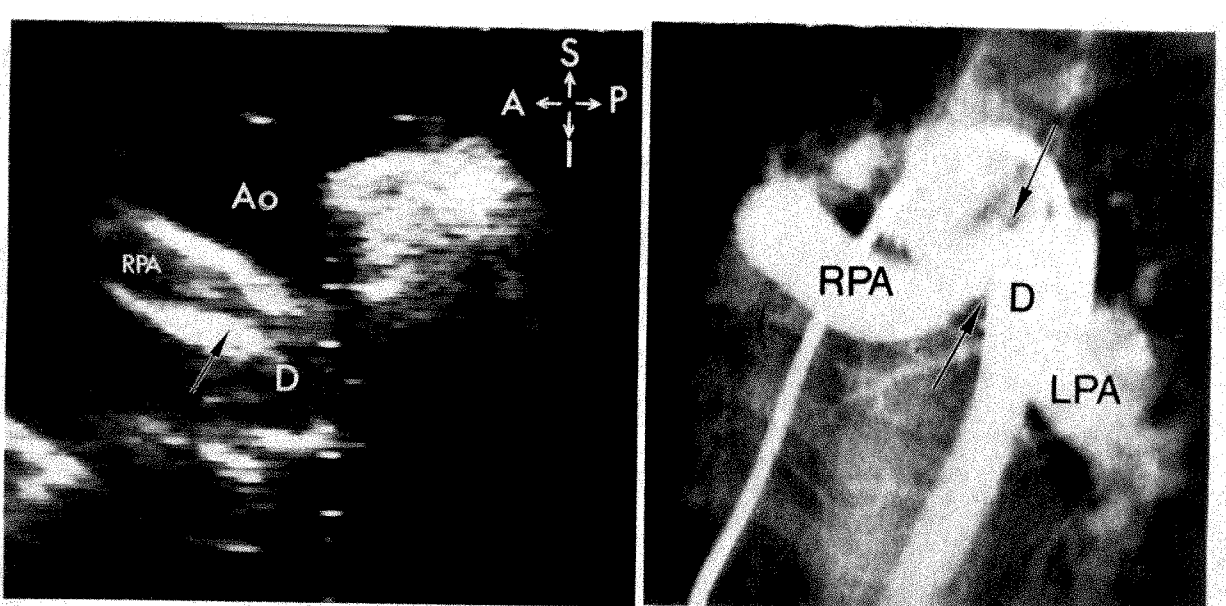

FIGURE 5. Left, angiogram (Case 4, type IV truncus arteriosus). Injection into the descending aorta (D) demonstrates (**arrows**) mild stenosis of the proximal right pulmonary artery (RPA), which is large in caliber. The left pulmonary artery originates from a more distal position on the descending aorta. **Right,** suprasternal notch echocardiogram (Case 8) clearly imaging the transverse aorta, descending aorta, and right pulmonary artery with proximal stenosis. LPA = left pulmonary artery; other abbreviations as before.

structures and extracardiac vessels and their connections can be imaged. The early bifurcation of the pulmonary artery can be used to identify this structure as it emerges from the left ventricle in patients with complete transposition.[9] Similarly, the origin of both great arteries from the right ventricle can be demonstrated with this approach. The subcostal sagittal plane image allowed identification of the aortic arch and origin of the pulmonary arteries from the truncus in our patients with truncus types I or II and truncus arteriosus with interrupted aortic arch.

The suprasternal notch view reliably identifies the great arteries leaving the cardiac chambers and their mutual relationships.[10] The situs of the aortic arch was reliably identified and incomplete septation of the aortic arch was detected in our patient with an aorticopulmonary window. The right pulmonary artery can often be visualized from this approach, but the left pulmonary artery is often not seen because of ultrasound reflections by intervening lung tissue.

It is important to use multiple imaging planes to substantiate the diagnosis of truncus arteriosus. Although the distal pulmonary arteries cannot be visualized, the proximal connections with the truncus arteriosus, the ventricular septal defect, and the situs of the aortic arch can each be reliably demonstrated. Although we were able to correctly establish the diagnosis of truncus arteriosus in the 7 infants in our series, we could not distinguish type I from type II, since a short segment of intervening main pulmonary artery was suggested from echocardiographic images even in the 3 patients with type II anatomy. This differentiation can at times even be difficult angiographically but would be apparent at the time of surgery and would modify somewhat the surgical approach to pulmonary artery banding or conduit placement with primary repair. The prospective diagnosis of common truncus arteriosus can be reliably established by 2-dimensional echocardiography; if necessary, subsequent invasive studies may then be performed more expeditiously with less contrast agent and hence greater safety in infants who are critically ill.

Two-Dimensional Echocardiographic Features of Interruption of the Aortic Arch

THOMAS W. RIGGS, MD, TERESA E. BERRY, MD, KALIM U. AZIZ, MD, and MILTON H. PAUL, MD

The 2-dimensional echocardiographic features of interruption of the aortic arch are presented based on analysis of the echocardiograms and angiograms from 8 infants: 2 with type A and 6 with type B interruption. Each infant had a patent ductus arteriosus, 6 had a conoventricular septal defect with leftward deviation of the conal septum, 1 had truncus arteriosus with truncal valve stenosis, and 1 had a distal aortopulmonary septal defect with an intact ventricular septum. Echocardiographic images obtained from the suprasternal notch or from a high parasternal approach demonstrated the interruption of the aortic arch and continuation of the patent ductus arteriosus into the descending aorta. These findings were compared with those in infants with aortic atresia and a hypoplastic ascending aorta or discrete coarctation of the aorta with tubular hypoplasia of the aortic arch. Types A and B interruption of the aortic arch were easily differentiated and the caliber of the patent ductus arteriosus was assessed. The characteristic conoventricular septal defect was readily visualized from an apex 2-chamber view or from a subcostal sagittal plane view. With this information subsequent angiography can be more expeditiously performed in this group of critically ill infants.

Two-dimensional echocardiography provides noninvasive visualization of the great arteries emerging from the heart and their mutual relations. Atresia or stenosis of the semilunar valves can be readily detected. The situs of the aortic arch can be established and the presence of supravalvular aortic stenosis or coarctation of the aorta can be determined.[1-5]

This report characterizes the 2-dimensional echocardiographic features of interruption of the aortic arch, based on experience with 8 infants. In previous reports individual patients with interruption of the aortic arch have been described,[1-6] but our series of 8 neonates demonstrates further that the morphologic diagnosis of interruption of the aortic arch type A or B can be made by echocardiography. The presence of an associated patent ductus arteriosus or ventricular septal defect was also demonstrated by echocardiography. We compare these findings with those in (1) a neonate with aortic atresia and hypoplasia of the ascending aorta, and (2) a neonate with aortic coarctation and tubular hypoplasia of the aorta.

Methods and Patients (Table I)

All patients underwent 2-dimensional echocardiographic examinations using an Advanced Technology Laboratory 2-dimensional sector scanner with a 5.0 MHz transducer. Most of the images were obtained in standard echocardiographic planes[7] and were displayed according to the usual angiographic orientation. Minor angular or positional variations from standard imaging positions are elaborated under Results.

In each infant, the echocardiographic examinations were completed before invasive studies. The diagnosis of aortic arch interruption was correctly made prospectively in all patients except Case 4. In this patient, early in our experience, the image of a widely patent ductus arteriosus was confused with that of an intact aortic arch (see Discussion). In retrospect, the interruption was obvious. This report includes our experience with interruption of the aortic arch over a 2-year period; the aforementioned case was the only diagnostic error.

Seven patients underwent cardiac catheterization and angiography. In Case 9, the anatomic diagnosis of aortic atresia was confirmed at postmortem examination. Three of the in-

fants were considered to have the clinical diagnosis of DiGeorge's syndrome (Cases 3, 4, and 6) and 1 infant (Case 2) had Down's syndrome.

Results

Suprasternal notch or high parasternal view: The suprasternal notch or high parasternal view correctly established the morphologic diagnosis of interruption of the aortic arch in all 8 cases. In addition to the obvious interruption of the aortic arch, the morphology of the ascending aorta and its arterial branches was characteristic for type A and type B interruption, and each was distinctly different from the aortic arch of a normal neonate. While the normal ascending aorta (Fig. 1) exhibits a continuous curvature to the descending aorta, the patients with either type A or B interruption had an ascending aorta with a straight course to its branches. This was most striking in the patients with type B interruption in which the ascending aorta simply bifurcated into the innominate and left common carotid arteries (Fig. 2). In the patients with type A interruption, the ascending aorta exhibited slight curvature and had 3 branches (Fig. 3). Anomalous origin of the right subclavian artery from the descending aorta was not appreciated by echocardiographic imaging in Cases 4 or 8.

From this approach, discrimination of interruption of the aortic arch from aortic atresia with a diminutive ascending aorta (Fig. 4) (Case 9) or from coarctation of the aorta and tubular hypoplasia of the aortic arch (Case 10) was possible (Fig. 5).

Parasternal sagittal view: This imaging plane, frequently utilized to examine the right ventricular outflow tract, pulmonary valve, and main pulmonary artery, was useful in imaging the patent ductus arteriosus. The caliber of the patent ductus arteriosus in relation to the descending aorta could be determined and the response to infusion of prostaglandin E_1 could be assessed in 4 patients (Cases 3, 4, 7, and 8) (Fig. 6 and 7).

Apex 2-chamber view: This imaging plane allowed optimal display of the conoventricular septal defect in 6 cases.[8] The ventricular septal defect was oblique with respect to the plane of the ventricular septum and was invariably associated with leftward deviation of the conal septum and a variable degree of subaortic narrowing (Fig. 8). The ventricular septal defect could also be visualized from a subcostal sagittal approach.[9] In

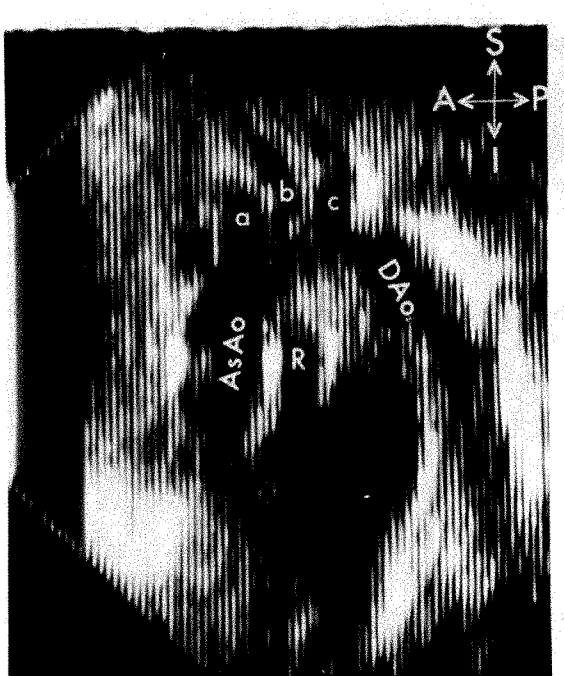

FIGURE 1. Echocardiogram obtained from a high parasternal notch approach, demonstrating a normal aortic arch with normal brachiocephalic branching. The patient has a normal heart and is 8 hours old. The echocardiogram is rotated to conform to the conventional angiographic display format. A = anterior; AsAo = ascending aorta; a = innominate artery; b = left common carotid artery; c = left subclavian artery; DAo = descending aorta; I = inferior; P = posterior; R = right pulmonary artery; S = superior.

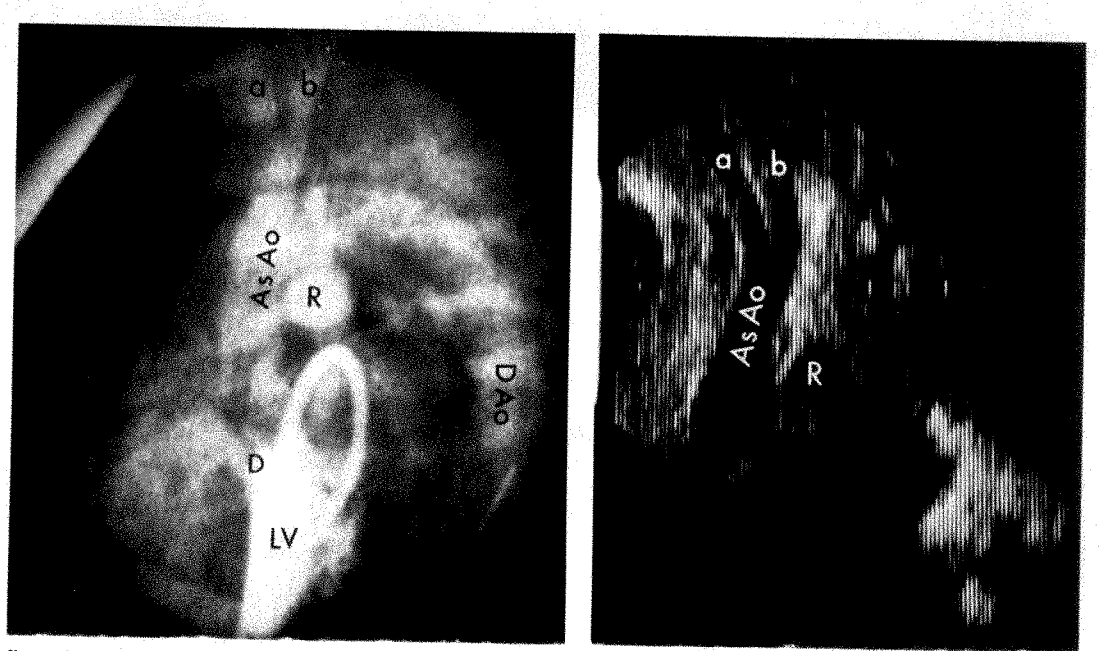

FIGURE 2. Left, angiocardiogram of left ventricle (Case 3) demonstrating interrupted aortic arch (type B) with ventricular septal defect and patent ductus arteriosus. The ascending aorta has a vertical course to its bifurcation into the innominate and the left common carotid arteries. **Right,** echocardiogram from a high parasternal position (Case 3), demonstrating bifurcation of ascending aorta into the innominate and left common carotid arteries with distal interruption of the aorta. AsAo = ascending aorta; a = innominate artery; b = left common carotid artery; D = ventricular septal defect; DAo = descending aorta; R = right pulmonary artery.

Case 7, the intact ventricular septum was correctly identified by echocardiography. Careful imaging of the ascending aorta and pulmonary arteries failed to demonstrate an aorticopulmonary septal defect which was subsequently diagnosed at cardiac catheterization.

Parasternal long-axis view: This view was not particularly useful in establishing the morphologic diagnosis of interruption of the aortic arch. Although the conoventricular septal defect was frequently appreciated in this view, the defect was better visualized from

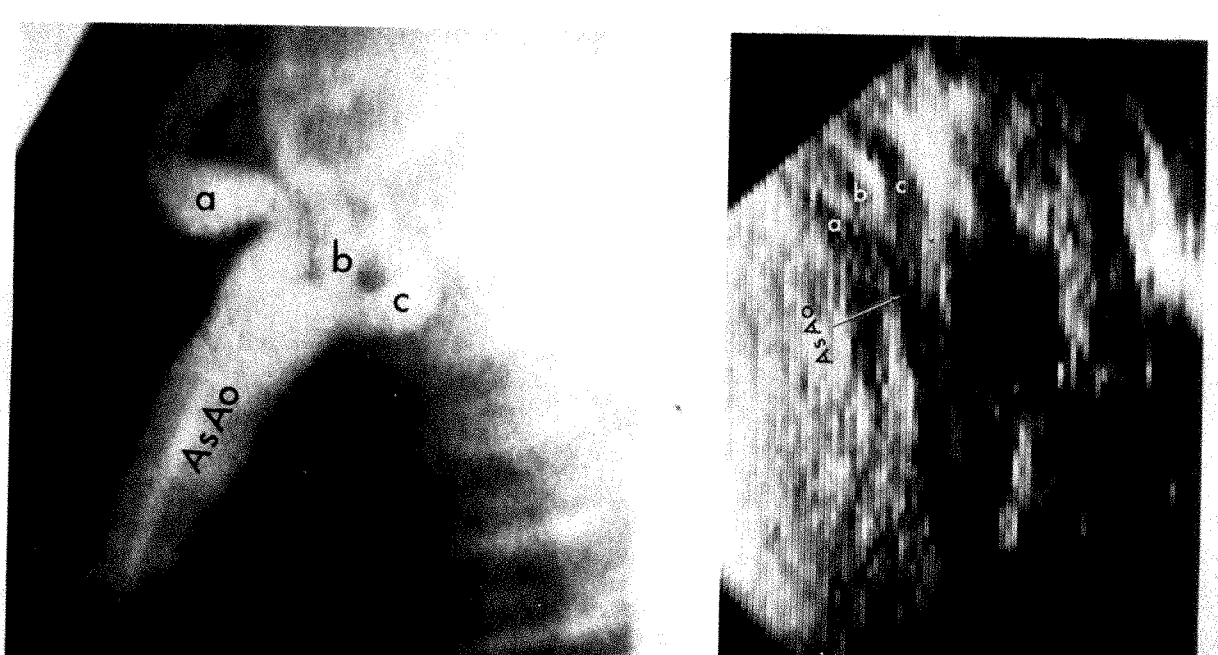

FIGURE 3. Left, selective angiogram of ascending aorta (Case 2) via the ventricular septal defect, demonstrating the interruption distal to the left subclavian artery (type A). **Right,** echocardiogram from a high parasternal approach, demonstrating 3 branches from the ascending aorta with interruption distal to the left subclavian artery (Case 2). Orientation of image as in Figure 2. AsAo = ascending aorta; a = innominate artery; b = left common carotid artery; c = left subclavian artery.

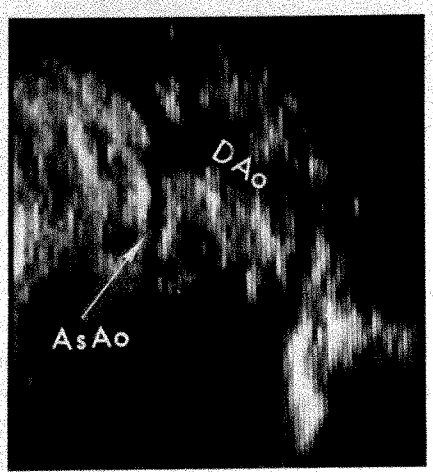

FIGURE 4. Parasternal echocardiogram obtained from a neonate with aortic atresia, confirmed at autopsy examination. The ascending aorta is very small (3 mm diameter) (Case 9). AsAo = ascending aorta; DAo = descending aorta.

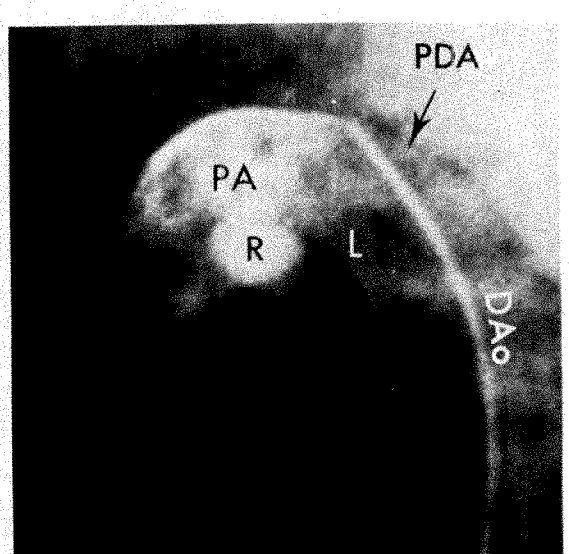
a subcostal or apical approach. In our 1 patient (Case 6) with truncus arteriosus and truncal valve stenosis, this view demonstrated the valvular stenosis, the ventricular septal defect and the systemic arterial override.

Discussion

Interruption of the aortic arch, one of the most rapidly lethal forms of congenital cardiovascular disease, is amenable to surgical repair.[10–13] The symptomatic neonate with interruption of the aortic arch needs expeditious, prompt, and accurate diagnostic investigations in preparation for surgery. A distinctive conoventricular septal defect with leftward deviation of the crista supraventricularis is frequently present in patients with interruption of the aortic arch, but aorticopulmonary window, common truncus arteriosus, or other cardiovascular malformations may also be present.[10,14,15] Rarely, interruption of the aortic arch



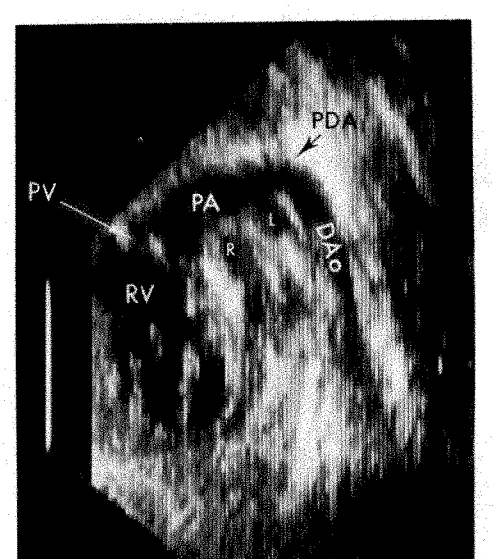


FIGURE 6. Left, lateral angiogram of injection via umbilical artery catheter into pulmonary artery. The ductus arteriosus (**arrow**) is widely patent. The patient was receiving prostaglandin E_1 to dilate the ductus arteriosus (Case 7). **Right,** Parasternal echocardiogram obtained in a sagittal plane (Case 7), demonstrating the large patent ductus arteriosus (**black arrow**) and its continuation into the descending aorta. The pulmonary valve (**white arrow**) is in the diastolic position. DAo = descending aorta; L = left pulmonary artery; PA = main pulmonary artery; PDA = patent ductus arteriosus; PV = pulmonary valve; R = right pulmonary artery; RV = right ventricle.

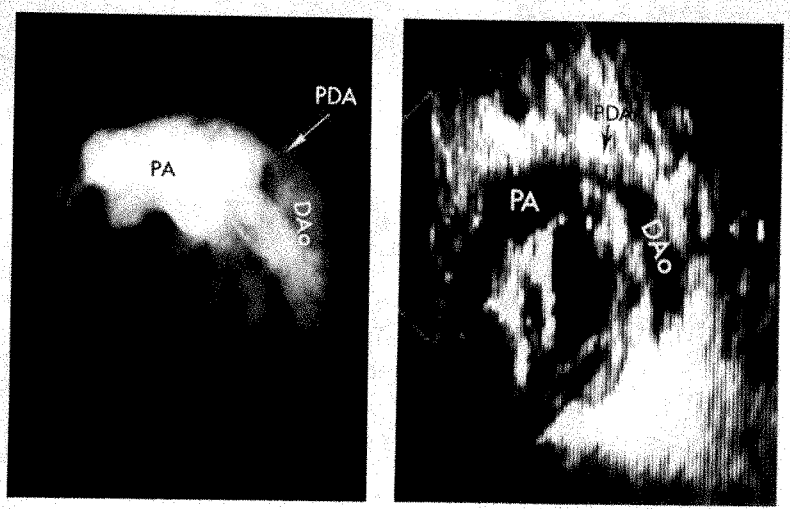

FIGURE 7. Left, lateral angiogram of pulmonary artery injection (Case 1) with demonstration of a small, restrictive patent ductus arteriosus. **Right,** parasternal echocardiogram obtained in a sagittal plane (Case 1), demonstrating the pulmonary artery, descending aorta, and closing patent ductus arteriosus. DAo = descending aorta; PA = main pulmonary artery; PDA = patent ductus arteriosus.

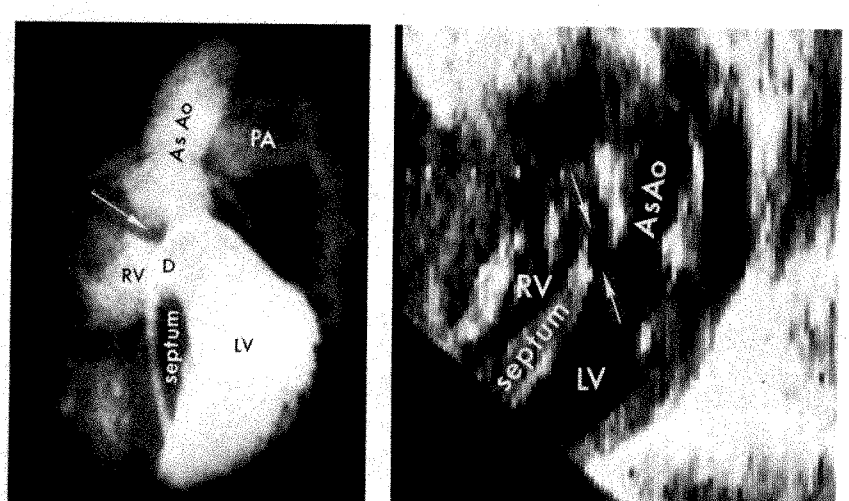

FIGURE 8. Left, Angiocardiogram of left ventricle (Case 4), showing ventricular septal defect and leftward deviation of the crista supraventricularis (**arrow**). This may result in subaortic stenosis, particularly after closure of the ventricular septal defect. **Right,** echocardiogram (apex 2-chamber views in Case 4), demonstrating the subaortic ventricular septal defect oriented obliquely (**arrows**) in the ventricular septum with leftward deviation of the crista supraventricularis. is an isolated lesion. In 2 review series, only 10 of 260 patients had isolated interruption of the aortic arch and all 10 were asymptomatic during infancy.[13,16] The noninvasive evaluation of the symptomatic neonate with interruption of the aortic arch should therefore establish both the morphologic diagnosis of aortic arch interruption and the details of associated cardiac defects.

Two-dimensional echocardiography allows imaging of the aortic arch and its branches. Previous studies have established the utility of this technique in the diagnosis of coarctation of the aorta or supravalulvar aortic stenosis.[1,4] Our present study demonstrates that the morphologic diagnosis of interruption of the aortic arch can be established by echocardiography. Coarctation of the aorta, with or without tubular hypoplasia of the aortic arch and the diminutive ascending aorta of aortic atresia, can each be readily differentiated from interruption of the aortic arch. In our experience, the hypoplastic ascending aorta in aortic atresia can almost always be imaged. In interruption of the aortic arch, the frequently associated conoventricular septal defect, as well as the leftward deviation of the crista supraventricularis, could be readily visualized from the subcostal or apical approach. Certainly, the presence of an intact ventricular septum in the patient with interruption of the aortic arch should alert the echocardiographer to consider carefully other diagnoses such as proximal or

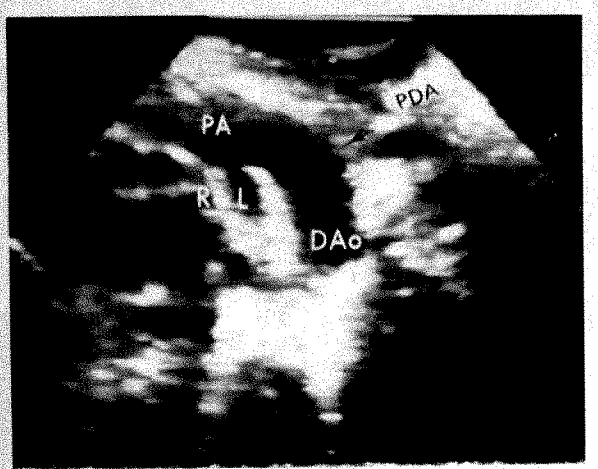

FIGURE 9. Echocardiogram obtained from suprasternal notch in a neonate with aortic atresia and a large patent ductus arteriosus (Case 9). A composite image of the pulmonary artery, patent ductus arteriosus, and descending aorta may be confused with an aortic arch. However, as seen here, the pulmonary artery branches (right and left) arise from the lesser curvature whereas the initial branches of the aorta arise from the greater curvature. DAo = descending aorta; L = left pulmonary artery; PA = main pulmonary artery; PDA = patent ductus arteriosus; R = right pulmonary artery.

distal aorticopulmonary window or anomalous origin of 1 pulmonary artery from the ascending aorta.[17]

The caliber of the patent ductus arteriosus and its response to the infusion of prostaglandin E_1 can be assessed by echocardiography, since the patent ductus arteriosus and descending aorta can easily be imaged in patients with interruption of the aortic arch. Care must be taken to differentiate an intact aortic arch from a composite image representing the main pulmonary artery, ductus arteriosus, and descending aorta structures, which can superficially mimic a normal aortic arch (Fig. 9). Careful observation of this composite image will disclose that its branches arise from the inferior aspect of this "arch" while the aortic arch gives origin to its first branches from its superior aspect. Furthermore, the origin of the main pulmonary artery can be related to the right ventricle.

Our experience indicates that 2-dimensional echocardiography can readily establish the morphologic diagnosis of interruption of the aortic arch, allow differentiation of type A from type B, and visualize the frequently associated conoventricular septal defect. In addition, the caliber of the patent ductus arteriosus can readily be assessed. Subsequent invasive studies may be more expeditiously performed in this group of critically ill infants.

Acknowledgment: We acknowledge the technical echocardiographic assistance of Sue Pajcic and the secretarial assistance of Alison Edwards.

Addendum

Since submission of this report, 2 additional patients with interruption of the aortic arch (type B) were seen and correctly recognized before angiography.

QUANTUM

THE MANAGEMENT SYSTEM FOR PACEMAKER PATIEN

The Quantum Pacing System is a complete system of pacemaker patient management and care. Now, through the innovative use of advanced telemetry, a wide range of real-time pacing system operating data is at the physician's fingertips.

The complete set of Quantum management tools allows a greater degree of flexibility in patient care and provides more valuable data than ever before available. A full range of real-time, as well as programmed operating data, are instantly available to help the physician make better, faster clinical decisions. All the data may even be communicated transtelephonically.

This advanced telemetry, combined with over 10,000 programmable prescription combinations allows the physician to adjust the pacemal the precise needs of the patient for better r agement during all stages of treatment. In dition to a direct digital read-out, a perma copy of the data may be generated automa for easy reference and recordkeeping.

For better patient management, choose best technology has to offer. The Quantum Pacing System from Intermedics.

QUANTUM INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications term cardiac pacing include, but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) bloc in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bund block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting such symptoms as intractable, recurrent congestive heart failure; cerebral or renal in ciency; or recurrent drug-resistant tachyarrhythmias, and who have been shown to benefit from temporary cardiac pacing, are considered candidates for permanent cardiac pacing.

The indications for permanent pacing in cases of acute myocardial infarction have not yet been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence of symptoms, ventricular rate, the mechanism of the arrhythmias, and response to therapy. In general, symptomatic drug-resistant bradyarrhythmias that impair cardiac output are considered indication pacing in patients with acute myocardial infarction, regardless of infarct location.

PROCARDIA®

(NIFEDIPINE) *Capsules 10 mg*

PROCARDIA is the beginning of a new age in the treatment of angina:

The Calcium Age.

It is now known that calcium ions, working at the cellular level, regulate the degree of vasoconstriction and, thereby, play a critical role in the anginal attack.

PROCARDIA acts at the cell membrane to selectively block calcium access to the contractile process in the arterial cell.

Through this action, PROCARDIA manages:

—vasospastic angina, by preventing coronary artery spasm and increasing myocardial O_2 supply

—classical effort-associated angina, by dilatin peripheral arteries to reduce afterload and myocardial O_2 demand

—mixed angina, which involves elements of vasospastic and effort-associated angina

Like beta blockers, PROCARDIA reduces myocardial O demand. But, unlike these agents, PROCARDIA also increases myocardial O_2 supply to both normal and poststenotic areas[1] of the myocardium by preventing coronary artery spasm.

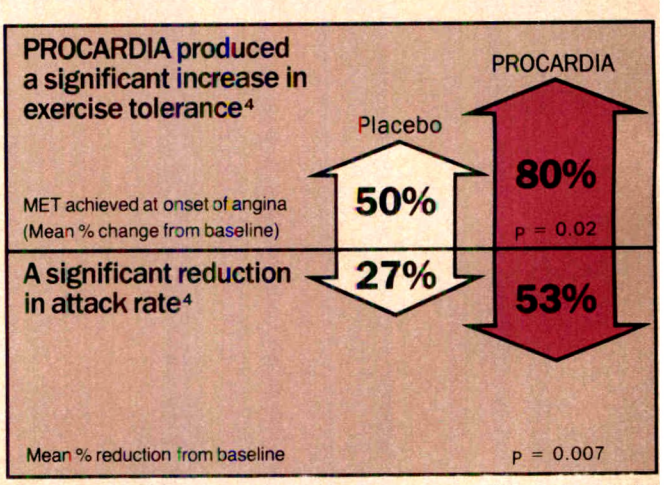
PROCARDIA
(NIFEDIPINE) *Capsules 10 mg*

PROVEN EFFECTIVE ACROSS THE SPECTRUM OF ANGINA

Contemporary medical opinion holds that the pathophysiology of angina is a spectrum ranging from pure, fixed atherosclerotic lesion to pure coronary artery spasm. Many patients, however, are believed to have a combination of both lesion and spasm.[2,3]

Angina due to pure fixed lesion can be prevented by reducing oxygen demand. Angina due to coronary artery spasm can be treated by preventing the spasm itself, thereby increasing oxygen supply. With this new understanding of angina, optimal antianginal therapy should provide this dual action: increasing O_2 supply while reducing O_2 demand.

In effort angina*
(when symptomatic despite conventional therapy)

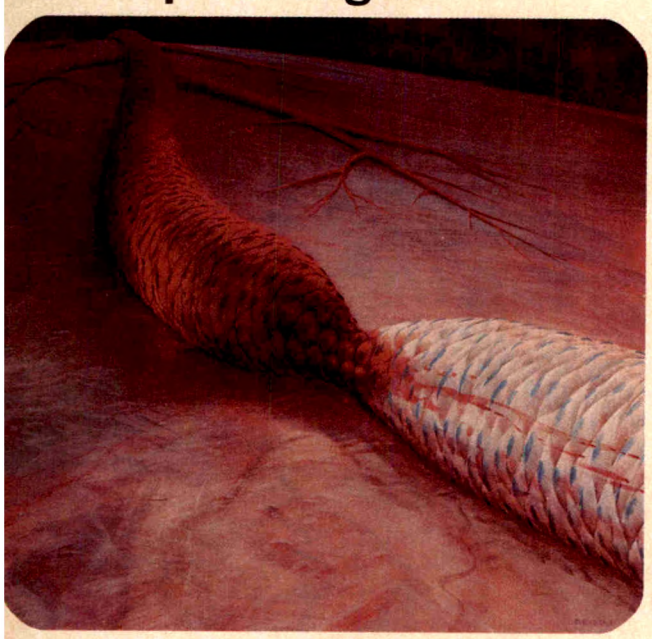


Double-blind, placebo-controlled, crossover 20-week study of 32 patients (27 evaluated for attack rate; 19 for exercise tolerance). Mean PROCARDIA dosage: 51 mg/day.

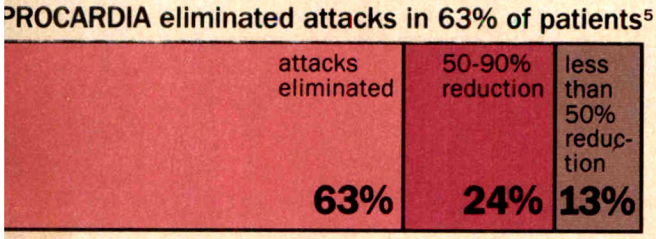
*In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA Brief Summary on last page

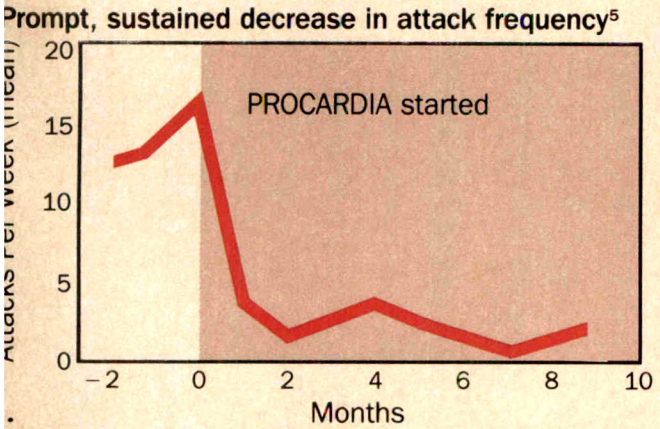
In vasospastic angina



PROCARDIA eliminated attacks in 63% of patients[5]

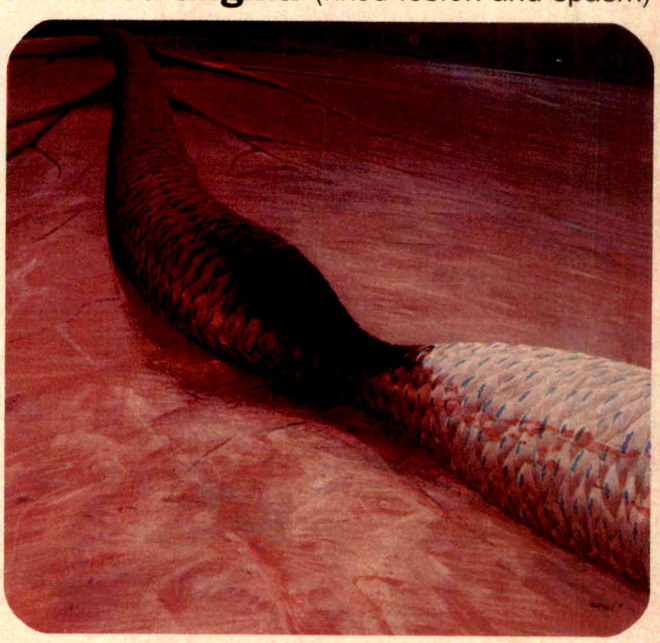


Prompt, sustained decrease in attack frequency[5]



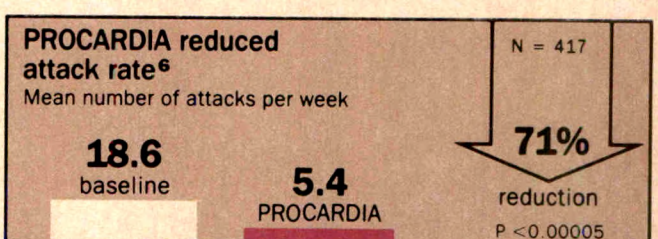
Long-term, open study of 127 patients unresponsive to beta blockers and/or nitrates with symptoms of myocardial ischemia and demonstrated coronary artery spasm. PROCARDIA dosage: 40 to 160 mg/day.

In mixed angina (fixed lesion and spasm)



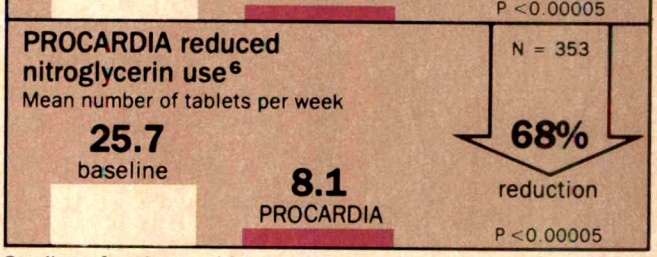
PROCARDIA reduced attack rate[6]

Mean number of attacks per week



PROCARDIA reduced nitroglycerin use[6]

Mean number of tablets per week



Studies of patients with mixed angina characterized by pain at rest and effort. Most patients (89%) were initiated on nitrate and/or beta blocker therapy but remained symptomatic. Minimum duration of nifedipine treatment two months. Nifedipine dosage: 30 to 120 mg/day.

PROCARDIA®

THE FIRST ORAL CALCIUM CHANNEL BLOCKER

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

ANGINA MANAGEMENT BEYOND BETA BLOCKERS

—Beta blockers prevent angina primarily by lowering myocardial oxygen demand. Like these agents, PROCARDIA reduces myocardial oxygen demand. However, PROCARDIA provides an added dimension of angina control by increasing myocardial oxygen supply where coronary artery spasm is present.

—Beta blockers can actually cause spasm. PROCARDIA prevents spasm.

—Beta blockers decrease myocardial perfusion in poststenotic areas. PROCARDIA increases myocardial perfusion to both normal and poststenotic areas.

—Beta-blocker treatment is limited in patients with myocardial dysfunction, COPD, asthma, bundle branch blocks, and diabetes. PROCARDIA can be given safely in all these groups of patients.

—The hypotensive effect of PROCARDIA is usually modest and well tolerated, however, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or subsequent upward dosage adjustment, and may be more likely with concomitant beta blockers.

—Occasional patients have developed well-documented increased frequency, duration or severity of angina on starting PROCARDIA, or at the time of dosage increases. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers, if possible, rather than stopping them abruptly before beginning PROCARDIA.

—Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

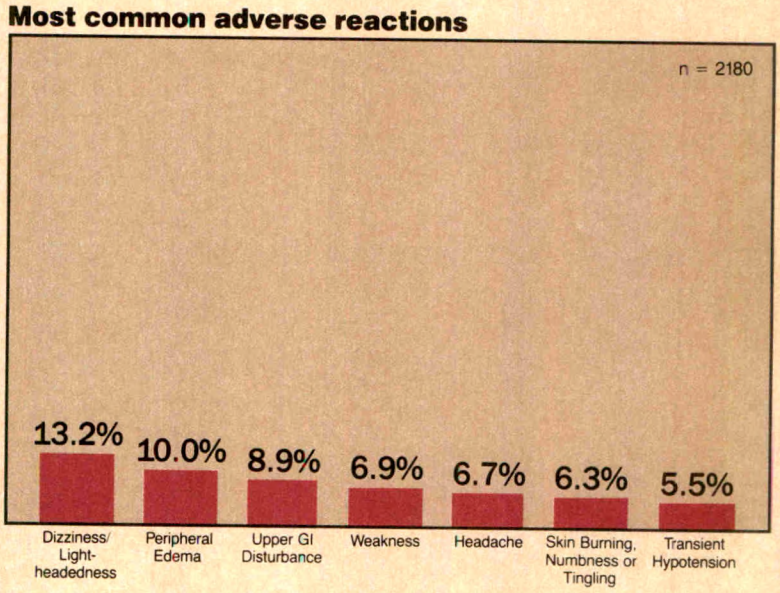
PROVIDES PROTECTION WITH A MILD SIDE-EFFECT PROFILE

Most common adverse reactions



Information is drawn from a large uncontrolled experience in 2180 patients and presents the most frequent side effects reported with PROCARDIA.

AN ADDED ADVANTAGE: COMPATIBILITY

—MAY BE USED WITH A WIDE VARIETY OF OTHER AGENTS

—CAN BE USED WITH NITRATES AND BETA BLOCKERS WITH CAUTION (See Warnings and Precautions)

THE FIRST ORAL CALCIUM CHANNEL BLOCKER FOR THE MANAGEMENT OF ANGINA

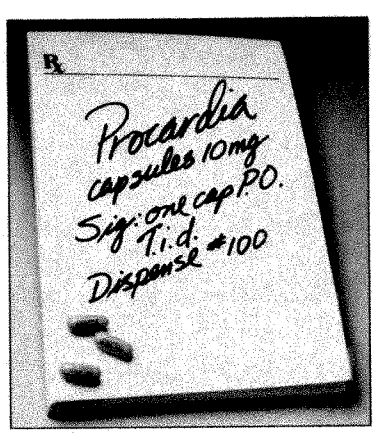
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Proven effective when used alone.

Enhanced effectiveness when combined with beta blockers.

Convenient dosing

Start with:	1	10-mg capsule *t.i.d.*
Titrate to:	2	10-mg capsules *t.i.d.*
Titrate to:	3	10-mg capsules *t.i.d.*



For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely. Maximum dose: 180 mg/day.

PROCARDIA® CAPSULES
(nifedipine)

For Oral Use

BRIEF SUMMARY

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Increased Angina/Beta Blocker Withdrawal: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Pregnancy: Category C.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA Capsule contains 10 mg of nifedipine. PROCARDIA Capsules are supplied in amber glass bottles of 100 capsules (NDC 0069-2600-66).

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

A Simple Teaching Device for Examination of the Arterial and Venous Pulse

ARTHUR KREITENBERG, MD, JOEL S. KARLINER, MD, ROBERT L. ENGLER, MD, and E. ROGER MARCHAND, PhD

A simple teaching device is described for examination of the cervical arterial and venous pulses. It is a mechanical device that simultaneously generates a visible jugular venous pulsation and a palpable carotid arterial pulsation to train medical students, physicians, and paramedical personnel. Changing of cams allows the observer to appreciate these pulsations in the normal or in a variety of abnormal states. Graphic tracings of wave forms demonstrate the accuracy of reproduction of physiologic tracings. In a test of the device, cardiologists performed significantly better than medical students in the identification of unknown pulsations. The instrument is readily accepted, simple to operate, and fully portable.

As part of the physical examination, study of the vessels of the neck may yield a great deal of information. The pulsations of these vessels are the most proximal superficial indicators of the state of the heart and vascular system.[1-6] Assessment of these pulsations is a usual part of a thorough cardiovascular physical examination. The importance and value of properly identifying and interpreting pulsations of the neck veins and arteries has been recognized since at least the year 200 AD.[3] In present-day intensive care units pressures and wave forms are often measured directly by insertion of catheters attached to the transducers. In these days of medical cost containment, it is increasingly important that the physician be able to assess, screen, and diagnose as accurately as possible the condition of the heart at the bedside using only his or her own eyes, ears, and hands.

The variations of normal and the spectrum of abnormal pulsations are subtle and best perceived only by the experienced clinician. Traditionally, this experience has been derived exclusively from patient contact and examination requiring many years of training. The device is intended as an adjunct to this training. The device described herein is designed to mimic the visual pulsations of the internal jugular vein and the palpable pulsations of the carotid artery in both health and disease.

Address for reprints: Office of Learning Resources, School of Medicine, University of Califonia at San Diego, La Jolla, California 92093.

The Instrument

Description: The device (Fig. 1) consists of 3 systems driven simultaneously by a single-gear motor. The mechanism mimicking the jugular venous pulse is on the right and the carotid pulse simulator is on the left. Small lights are used to mark the occurrence of the first and second heart sounds as well as any murmurs associated with pathologic conditions. The device does not reproduce these sounds audibly.

The position of the examiner is similar to that for an actual physical examination. Situated on the right side of the device, as in the bedside examination, the examiner places a finger over the anatomic position of the carotid artery. Visual attention is directed at the tubing representing the internal jugular vein. As in the live patient these pulsations should be viewed tangentially. The small lights are observed to mark the occurrence of heart sounds or any murmurs. Tactile stimuli from the arterial pulse as well as the heart sounds are used for proper identification and interpretation of venous pulsations.

The cams (Fig. 2) are carefully designed and shaped to reproduce accurately and reliably the various normal and abnormal pulsations. The accuracy of reproduction is demonstrated by graphic tracings (Fig. 3) obtained from the device with an external pulse recorder and comparison with knowledge of physiologic recordings from patients.[1-6]

The pulsations currently available are listed in Table I. Cams are easily changed within seconds to reproduce the desired abnormality.

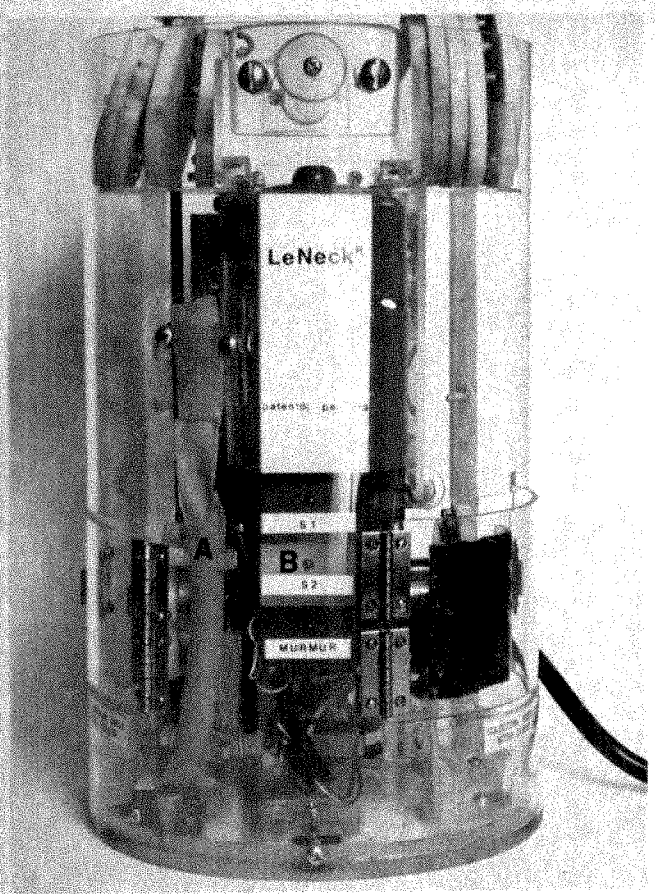

FIGURE 1. The instrument is the approximate size and shape of a human neck. **A**, visible venous pulsations. **B**, lights marking the occurrence of heart sounds. **C**, palpable arterial pulsations.

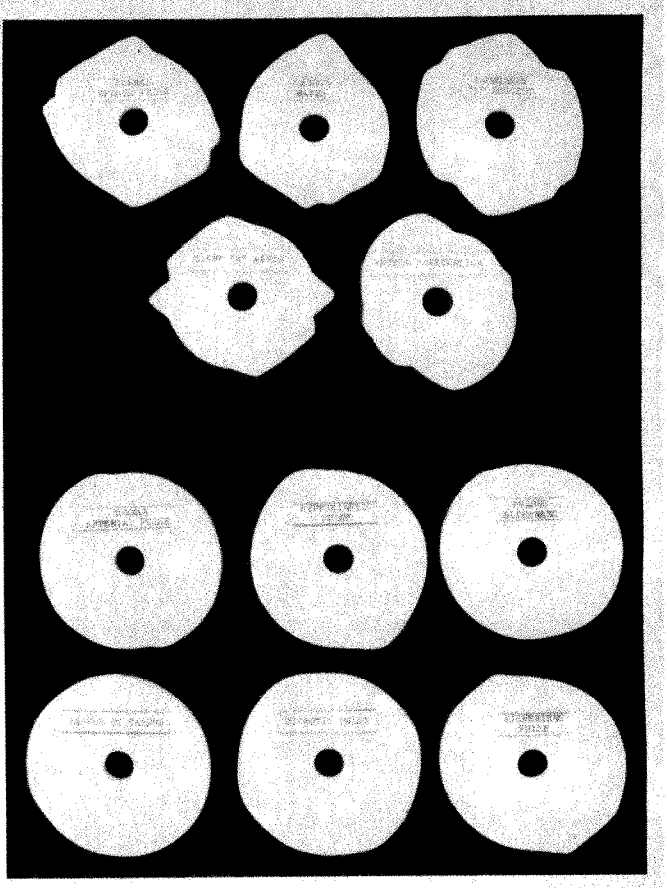

FIGURE 2. The cams are carefully shaped to reproduce the appropriate wave forms.

The device is designed to be portable and needs only a standard electrical outlet. Experience with medical students shows that the device is readily accepted and simple to operate.

Assessment: A study was performed to objectively assess this new teaching tool. Because it is logistically difficult to assess the learning of a physical examination skill, we elected to determine whether the device indicates a person's present level of that skill. We therefore compared the performances of a group of cardiologists with a group of third and fourth year medical students. Both groups have a knowledge and understanding of the pulsations. However, the cardiologists were certified by the Internal Medicine Board and had specialty training in cardiology and clinical experience.

TABLE I Number Correct for Each Pulse

	Cardiologists Correct (n = 11)	Medical Students Correct (n = 14)
Venous		
Cannon waves	11	7
Normal venous	4	5
Bogus	2	0
Giant *a* waves	5	9
Prominent *y* descent	7	5
Ventricularization	9	7
Arterial		
Dicrotic	8	10
Pulsus alternans	11	13
Normal arterial	10	12
Hyperkinetic pulse	11	13
Bisferiens pulse	9	7
Parvus et tardus	10	12

TABLE II Distribution of Scores (Number Correct Out of 12)

Score	Cardiologists (n)	Medical Students (n)
12	1	0
11	2	0
10	4	1
9	2	1
8	1	6
7	1	2
6	0	1
5	0	2
4	0	0
3	0	0
2	0	1
1	0	0
0	0	0
Total	11	14
Mean	9.73	7.07
SD	1.42	2.02
Var	1.84	3.78

F test of 3.18 ($p < 0.01$) and *t* test of 3.54 ($p < 0.01$) between mean scores of the 2 groups. SD = standard deviation; VAR = variance.

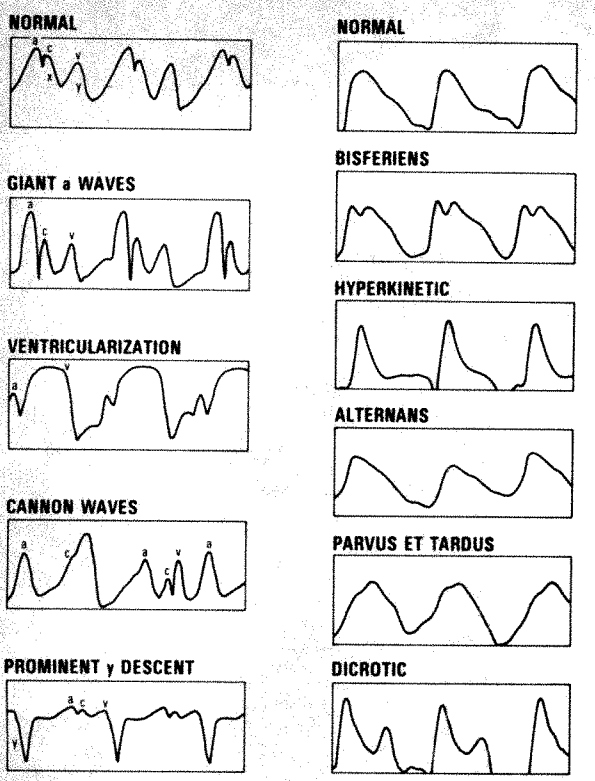

FIGURE 3. Neck venous (**left**) and arterial (**right**) pulses: graphic tracings of waves generated by the device, recorded with a clinical external pulse recorder.

Name labels on the cams were removed. Venous cams were labeled 1 through 6 and arterial cams were labeled 7 through 12. One cam (venous) was bogus. The examiner attempted to identify each arterial and venous pulse on a test sheet (Table I). All testing was supervised by the same person (AK). Each subject was given the following set of rules: (1) There is at least 1 (of the 12) bogus pulse; (2) no choice is used more than once; (3) you may return to any cam to recheck your answer; and (4) the variable speed control may be used. The device was initially set at a rate of 70 beats/min. Arterial pulsations were tested first. Then, the normal arterial cam was disclosed and used in the identification of the venous pulsations.

Results

Table II shows the distribution of scores (number correct out of 12) for each group. The cardiologists performed better than the medical students. The difference between the 2 groups is significant at the $p = 0.01$ level.

Table I displays the same data by pulse for each group. Analysis of these data shows several interesting points. There was a significant difference in the 2 groups interpreting venous pulsations but no significant difference in interpreting arterial pulsations. The largest differences between the groups occurred when the following pulses were tested: cannon waves, prominent y descents, ventricularization, and bisferiens pulse. The pulses most often correctly identified were the pulsus alternans and the hyperkinetic pulse. The pulses least often correctly identified were the bogus and the normal venous pulses; these were correctly identified by less than half in each group.

Analysis of individual test sheets showed that the most commonly confused pair were the double-peaked arterial pulses, bisferiens and dicrotic. This error was made by 2 cardiologists and 3 medical students.

Discussion

The results of the assessment demonstrate that trained cardiologists can effectively recognize most of the pulses mimicked by the device, and that training enhanced the identification of venous pulses mimicked by the device. The fact that a greater difference was seen when testing the venous than when testing the arterial pulsations may be attributed to a number of factors. Among these are greater ease in learning the arterial rather than the venous examination and technical factors involving the device or study.

A subjective conclusion that may be drawn from the present study is the acceptance of the device by the subjects. It was viewed as fun, worthwhile, and valuable. The device has shown itself to be practical and easily operated.

Conclusions: The device has been named "LeNeck" (patent pending). The design is original and unique. LeNeck is likely to be a useful teaching aid. Direct visualization of venous pulses and palpation of arterial pulses of rare prevalence will be especially useful to students with limited contact with uncommon abnormalities. The device is intended to be an adjunct to proper and thorough training of physicians and other health care professionals.

Acknowledgment: This device was developed as an independent medical student study project by Arthur Kreitenberg with support from the University of California, San Diego, School of Medicine, Office of Learning Resources.

Evaluation of Pulmonary and Systemic Blood Flow by 2-Dimensional Doppler Echocardiography Using Fast Fourier Transform Spectral Analysis

STANLEY J. GOLDBERG, MD, DAVID J. SAHN, MD, HUGH D. ALLEN, MD, LILLIAM M. VALDES-CRUZ, MD, HEINZ HOENECKE, BA, and YVONNE CARNAHAN, BS

This study was designed to assess the accuracy and problems of noninvasively measuring right and left cardiac output by range-gated pulsed Doppler echocardiography. Sixteen children with cardiac disease, aged 3 months to 17 years, served as the subjects; 2-dimensional range-gated pulsed Doppler echocardiographic data were unobtainable in 2 children, leaving 14 for study. Diagnoses included shunt lesions, valvular abnormalities, coarctation, repaired defects, and Kawasaki's disease. The equipment for this study included a 2-dimensional echocardiographic Doppler sample volume locator. The Doppler frequency shift was analyzed by fast Fourier transform. Twenty 2-dimensional range-gated pulsed Doppler echocardiographic measurements (10 pulmonary and 10 aortic) were made simultaneously with indicator dilution outputs or angiographic outputs. In 4 subjects, 2-dimensional range-gated pulsed Doppler echocardiographic aortic outputs were not possible. For this study, vessel diameter was determined by both echocardiography and angiography, Doppler intercept angle by 2-dimensional echocardiography, and velocity by 2-dimensional range-gated pulsed Doppler echocardiography. Comparison of cardiac output measurements obtained by invasive methods and by 2-dimensional range-gated pulsed Doppler echocardiography (angiographic vessel measurement) showed a correlation of +0.94 (standard error of the estimate [SEE] = 0.53) with a slope of y = 0.83 × +0.61, indicating that the slope and line of identity were almost equal and the offset from 0 was small. For 2-dimensional range-gated pulsed Doppler echocardiography (echocardiographic vessel measurement), the correlation was +0.94 for aortic flow but only +0.72 for pulmonary flow. Problems encountered in some patients included turbulence, which made velocity measurements unreliable, difficulty in obtaining aortic flow by Doppler echocardiography due to transducer configuration, and measurement of pulmonary diameter by echocardiography. The results indicate that 2-dimensional range-gated pulsed Doppler echocardiographic outputs are accurate under conditions of nonturbulent or minimally turbulent flow and adequate imaging, but only when vessel diameter can be accurately measured.

Major interest in cardiac output measurement by Doppler echocardiography began 2 decades ago with the demonstration that circumferential Doppler flow probes could measure blood velocity. During the past decade, advances in echocardiographic technology provided the stimulus to adapt Doppler flow measurements to insonation of the aorta from the body surface. Four measurements necessary to compute blood flow by Doppler include (1) blood velocity; (2) vessel area; (3) intercept angle between the Doppler beam and flow; and (4) heart rate. Initial attempts to measure blood flow with Doppler concentrated on continuous wave devices. Although results obtained with these devices were remarkably encouraging, several problems were identified: (1) Continuous wave Dopper measurement provides velocity information from all along the Doppler beam. This nonselectivity permits simultaneous collection of velocity information from desired and undesired locations. (2) The angle of intercept between the Doppler beam and the direction of flow was uncertain. Beam

TABLE I A Nonexhaustive Summary of Investigations Using Aortic or Pulmonary Flow Measurements or Approximations, or Both

Author	Population	Doppler Type	Frequency Analysis	Placement Doppler SV	Flow Comparison	Doppler Output	Measurement Site
Darsee et al[1]	20 dogs	CW	ZCD	Max signal	EM catheter	Volume flow	AO
Colocousis et al[2]	6 dogs	CW	Not stated	Max signal SSN or by direct placement on aorta	Thermal	Systolic velocity integral	AO
Sequeira et al[3]	20 human subjects	CW	Not stated	Max signal	ID, EM catheter	Volume flow	AO
Huntsman et al[4]	7 human subjects	CW	Kay sonograph envelope detector	Max signal	Not studied	Velocity	AO
Darsee et al[5]	29 patients	CW	ZCD	Max signal	Fick and thermal	Volume flow	AO
Griffith and Henry[6]	20 human subjects	Pulsed	True spectral	2D echo	None	Velocity	AO
Magnin et al[7]	11 human subjects	Pulsed	ZCD	2D echo	Fick, but at another time	Volume flow	AO
Steingart et al[8]	6 dogs	Pulsed	ZCD	Direct placement on aortic arch	EM	Systolic frequency shift integral	AO
Angelsen and Brubakk[9]	18 human subjects	Pulsed	Frequency estimation	Max signal	None	Velocity	AO
Goldberg et al	16 human subjects	Pulsed	FFT	2D Echo	ID	Volume flow	AO + PA

AO = aorta; CW = continuous wave Doppler; EM = electromagnetic; FFT = fast Fourier transform; ID = indicator dilution; max signal = maximal signal; PA = pulmonary artery; pulsed = range-gated pulsed Doppler; SSN = suprasternal notch; SV = sample volume; 2D echo = 2-dimensional echocardiography; ZCD = zero crossing detector.

direction was adjusted to record the maximal available signal and an angle of 180° was assumed. (3) Linear frequency analysis of the Doppler shift was technically difficult to measure, so a zero crossing detector was employed to plot a time interval histogram of the average flow at each point in time. Zero crossing detectors are nonlinear devices because they cannot provide frequency analysis of a spectrum, although they work acceptably well for analysis of a single frequency, particularly if the signal is strong and the noise level is low. Despite these problems, systolic velocity and frequency intergrals, true systolic velocity, and cardiac output were shown to be measurable by the Doppler method.[1–5] A nonexhaustive list of previous work is contained in Table I.

Recent advances in technology have allowed a new generation of equipment to become available, some of which promise to solve certain of these problems. Pulsing of the transmitted signal allows range-gating so that Doppler information can be obtained from an isolated area selected by M-mode or 2-dimensional echocardiography. Early work with range-gated cardiac output measurement[6–9] is also summarized in Table I. Unfortunately, this advance causes the loss of detection of very high velocities which were possible with continuous wave Doppler but not with pulsed Doppler echocardiography. If the Doppler sample is located with 2-dimensional echocardiography, the angle between flow and the Doppler beam can be determined in 2 planes. Additionally, 2-dimensional echocardiography allows estimation of great vessel diameters. Finally, Doppler frequency shift can now be analyzed by fast Fourier transform, a technique that provides linear analysis at a present repetition rate of 200 samples/s. However, to date, we are unaware of published data that compare aortic or pulmonary blood flow, or both, as measured with this new generation of Doppler instrumentation, with blood flow measured with standard techniques.

The purpose of our study was to simultaneously measure right or left heart output in patients with (1) a range-gated pulsed Doppler device capable of frequency analysis by linear fast Fourier transform analysis, the sample volume of which was located with 2-dimensional echocardiography, and (2) an invasive technique for cardiac output determination, principally indicator dilution, for the purpose of comparing results of the 2 methods. A secondary purpose was to detail the problems encountered during Doppler cardiac output measurement.

Methods

The population consisted of 16 children who were undergoing clinically indicated cardiac catheterization. Diagnoses of individual patients is shown in Table II. Children with complex anomalies were excluded. This group of children was selected to allow accurate invasive determination of cardiac output by indicator dilution. A prototype range-gated pulsed Doppler unit (Electronics for Medicine, Honeywell) was used. This instrument provided a 2.5 MHz real-time 2-dimensional image achieved by sweeping a conventional single element transducer through a 60° arc. The equipment also provided an electrocardiographic trace, and a frequency analysis of the Doppler signal by fast Fourier transform.

The sample volume is the area within which the velocity of blood flow is sampled by the Doppler. In the prototype instrument, an adjustable position Doppler sample volume of operator-selectable length could be positioned along any information line of the 2-dimensional image. The width of the sample was determined by beam width at any sampling depth and was not under operator control. The location on the 2-dimensional image at which Doppler would be sampled was

TABLE II Individual Patient Data

Case	Diagnosis	Cardiac Output Doppler (Angio)	Doppler (Echo)	Invasive	Pulmonary Output Doppler (Angio)	Doppler (Echo)	Invasive CO
1	ASD primum	1.05	1.05	0.89	3.04	3.20	3.56
2	TOF (PO)	3.42	2.80	2.94	...	...	...

14	VSD (PO)	...	...	...	2.79	3.16	3.58

Note that each patient did not necessarily have an aortic and pulmonary flow measurement. AI = aortic insufficiency; angio = diameter measured by angiography; AS = aortic stenosis; ASD = atrial septal defect; CO = cardiac output; coarct = coarctation of the aorta; echo = diameter measured by echocardiography; PO = postoperative; TI = tricuspid insufficiency; TOF = tetralogy of Fallot; VSD = ventricular septal defect.

determined by automatically highlighting an information line within the 2-dimensional image along which the transducer would stop when the operational mode was switched from 2-dimensional echocardiography to range-gated pulsed Doppler. The depth and length of the sample volume were also superimposed on the image and on the Doppler outputs (Fig. 1). The Doppler sampling rate was 19,500 samples/s (maximal velocity ± 331 cm/s) at 0 to 4 cm and 9,750 samples/s at 4 to 8 cm (maximal velocity ± 161 cm/s). Once in the Doppler mode, 2 simultaneous outputs were available. The first was an audio signal, and the second was a fast Fourier transform spectral analysis of the Doppler signal which was sampled 200 times/s. Dopper output and an electrocardiographic tracing were recorded on a strip chart. The output of the fast Fourier transform was calibrated in Doppler shift frequency (Hertz) and directly converted by the instrument to velocity of flow calibrated in cm/s according to the following formula: Velocity = frequency shift × velocity of sound in the medium/2 × transmitted frequency × cos θ, where θ = the angle of incidence between the Doppler beam and flow direction.

Ultrasonic studies performed in the catheterization laboratory during the invasive procedure began with 2-dimensional imaging of the pulmonary artery from a precordial short axis transducer position. Images in this plane consist of the ascending aorta in cross-section and a long axis of the right ventricular outflow tract, main pulmonary artery, and its bifurcation. Once the appropriate image was found, the highlighted Doppler interrogation line was placed distal to the pulmonary valve and as parallel as possible to the center of the main pulmonary artery, and the Doppler sample volume was adjusted to 5 to 10 mm in length (Fig. 1). Care was taken to maintain the transducer in a steady position and the output of the fast Fourier transform was examined visually. Frequently, some transducer adjustment was necessary to optimize the recorded Doppler output within the main pulmonary artery. After an optimal Doppler signal was found and the Doppler interrogation line was confirmed to be within the main pulmonary artery, a 2-dimensional frame, gated in early systole, was photographed to verify the Doppler position and to allow later determination of the Doppler-flow intercept angle. The diameter of the pulmonary was measured, when possible, on this image with leading edge methodology at a portion of its sweep around the aorta near the insertion of the pulmonary valve where the vessel would be measured axially. However, in many patients axial measurement was impossible and an image similar to the one in Figure 1 was recorded. In these instances, gain was reduced until the walls of the pulmonary artery were as thin as possible and the measurement was made from inner to inner wall (no leading edges exist in this instance).

Next, the transducer was placed in the suprasternal notch, the ascending aorta was imaged, and the Doppler interrogation line was directed into the ascending aorta. The aortic diameter used for calculating aortic area by echocardiography was measured from M-mode traces of the aortic root derived from the short-axis 2-dimensional image. Sample volume length, beam positioning, and recording procedures were essentially similar to those already described for the main pulmonary artery.

Analysis of records: Cardiac output was computed according to the formula: Cardiac output = (mean velocity/beat × heart rate × vessel area)/cos θ. Mean velocity was measured by tracing the middle of the densest portion of the gray scale display output of the spectral analyzer along the systolic phasic velocity curve with an Apple computer (Cupertino, California) and a commercially available program (Biodata, Davis, California). For ≥5 beats, the velocity area was computed and this integral was divided by the average beat duration to provide the mean velocity. Mean heart rate for these beats was measured from the R-R interval. Great vessel diameter in each patient was measured from 2-dimensional echocardiographic images or the derived M-modes as just described and also from calibrated angiographic contrast studies of the great arteries obtained during the same catheterization procedure. Flow was assumed to be directed along the axis of the great vessel. The intercept angle between the Doppler beam and blood flow in the vessel was measured. Because 2-dimensional echocardiography was used to determine this angle within the plane, the angle between flow and Doppler interrogation in the third nonvisualized (elevational or azimuthal) plane was not taken into account.

Cardiac output by Doppler measurement was compared with simultaneous measurements by indicator dilution (thermal, 2 patients; Fox green dye, 17 patients) or in 1 instance by an angiographic technique as an average of the first 3 beats.

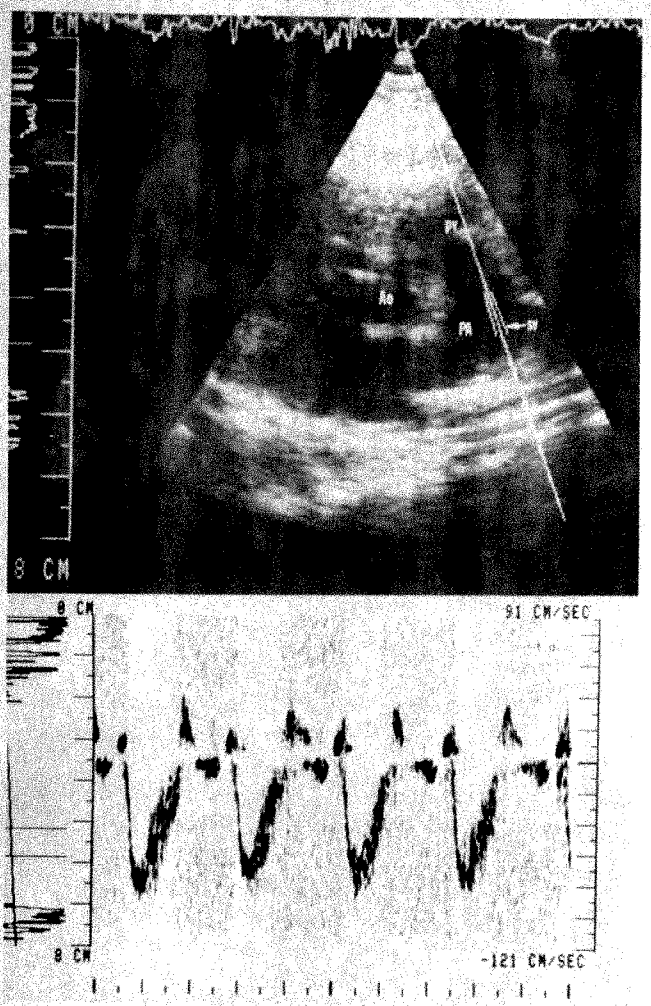

FIGURE 1. Top, a 2-dimensional echogram showing a small area of right ventricular outflow, pulmonary valve (PV), and main pulmonary artery (PA) and its branches. The sample volume (SV), shown by **parallel bars** flanking the Doppler indicator line, is in the main pulmonary artery. In this instance, we could not measure the pulmonary artery by axial resolution and the arterial borders are present but indistinct. This example demonstrates the problem with echocardiographic measurement of the pulmonary artery diameter. The **bottom panel** shows calibrated velocity within the pulmonary artery. Tracing of velocity for integration is obvious on the downslope; however, the precise area for tracing on the upslope is less obvious. We traced the center of the dense area on the upslope. The electrocardiogram is not shown on this velocity tracing. Ao = aorta.

Right or left ventricular outputs by indicator dilution were determined by the logarithmic extrapolation technique. Right heart output was measured by injecting into the pulmonary artery and sampling in the left atrium, left ventricle, or aorta, but always proximal to a shunt. Left cardiac output was measured by injecting into the pulmonary artery, left atrium, or left ventricle, and sampling in the aorta. Thermal cardiac outputs were measured in 2 patients without shunts by injecting cold saline solution into the right atrium and sensing the temperature change in the pulmonary artery. One patient had an angiographic cardiac output determined by modified Simpson's rule.[10] The angiographic and thermal techniques used in our laboratory show a variance of ±7% when compared with the green dye technique.

Results

Adequate imaging and Doppler data were obtained in 16 patients aged 3 months to 17 years. No patient had a velocity that exceeded the maximal velocity limits. Results of 2 patients were excluded because cardiac output measurement by indicator dilution was impossible because of blood withdrawal pump failure, leaving 14 patients in whom simultaneous Doppler and conventional cardiac output measurements could be made. In 4 instances, aortic flow measurement could not be made because of inability to image the ascending aorta adequately from the suprasternal notch. Doppler measurement of pulmonary flow was not attempted in 3 patients who had pulmonary valvular insufficiency. Pulmonary flow was not measured in another patient because of equipment failure after the aortic flow measurement. Data for each patient are shown in Table II.

Doppler measurement technique: The Doppler intercept angle with the great vessel, as imaged in 2 planes, proved easy to measure. Tracing the center of the densest portion of the velocity curve also proved to be easy and highly reproducible from person to person unless turbulence caused marked spectral dispersion. In that event, tracing was impossible. Aortic diameters were highly reproducible, but pulmonary artery diameters were difficult to measure. Figure 1 illustrates this problem. This image is representative of most of the patients. The anterior left border was frequently ill-defined, and the wall next to the aorta was only slightly more distinct. Variation in pulmonary artery size between frames of this patient measured 3.8 mm, a number representative of the entire group.

Flow measurements by Doppler using angiographically determined vessel diameter (Fig. 2): Flow, measured by Doppler in the pulmonary artery and aorta using angiographically determined vessel area and invasively measured flow, was statistically similar by Student's t test. The correlation between the 2 output measurement techniques was r = +0.94, SEE = 0.53 liters/min (Table III) for combined pulmonary and aortic measurements. Combination was appropriate because the individual correlation coefficients for the comparison of Doppler and invasive cardiac outputs were equal for pulmonary (r = +0.94) and aortic (r = +0.94) flow and because the respective slopes and intercepts were quite similar (0.86 and 0.31 [cardiac output] and 0.79 and 0.80 [pulmonary output]).

Doppler cardiac output measured with echocardiographically determined vessel diameter (Fig. 2): The correlation coefficient (r = +0.86) for invasively measured output and combined pulmonary and aortic Doppler determined output, using ultrasonically determined vessel size, was lower than that for Doppler flow obtained from angiographically determined diameters. Furthermore, the standard error of the estimate for the relation with vessel diameters measured by echocardiography was 830 ml, which was about 50% greater than the standard error of the estimate for vessel

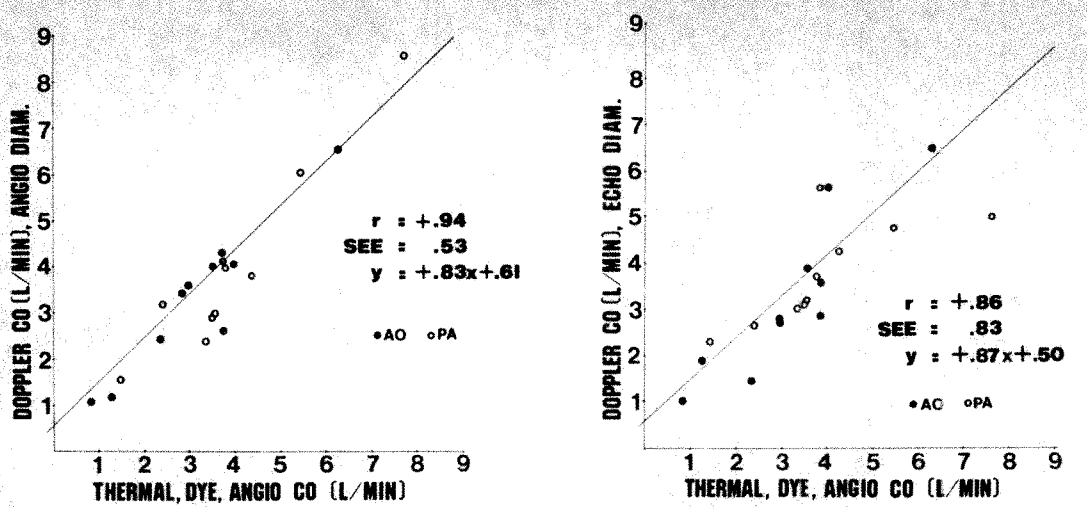

FIGURE 2. Left, results of Doppler cardiac output (CO) determined by angiographically determined vessel diameter (ANGIO DIAM) are compared with cardiac output determined by invasive measurements. **Right,** this illustration is essentially similar except that Doppler cardiac output was computed with vessel diameters measured from echocardiograms. SEE = standard error of the estimate (in liters/min); y = 0.83x +0.61, y = 0.87x +0.5 are slope formulas; other abbreviations as in Figure 1.

size determined by angiography. The correlation between cardiac output determined invasively and Doppler output determined with echocardiographically measured vessel diameter was poorer for the pulmonary artery (r = +0.72) than for the aorta (r = +0.91). This lower correlation for pulmonary flow resulted from the difficulty in measuring the pulmonary artery diameter by either 2-dimensional or M-mode echocardiograms derived from the 2-dimensional image, whereas the aortic diameter was relatively easy to measure.

Discussion

The unique feature of this investigation was that simultaneously measured range-gated pulsed Doppler pulmonary or systemic flows were compared with flows measured by accepted invasive techniques, principally the indicator dilution technique. Furthermore, in this study, spectral analysis of range-gated pulsed Doppler flow was accomplished by fast Fourier transform, which provided an accurate and linear frequency analysis of the Doppler signal. Our results indicate that the combination of 2-dimensional echocardiographic location of the Doppler sample volume, use of fast Fourier transform analysis, and accurate measurement of the vessel diameter provides right or left heart outputs that were comparable to values determined by commonly used invasive techniques.

Problem of pulmonary artery flow measurement: The major problem encountered during this investigation was the measurement of pulmonary artery diameter by echocardiography. Although the pulmonary artery could be imaged in several patients so that axial measurement of diameter was possible, in the remainder we obtained images similar to that shown in Figure 1. In this instance, the pulmonary artery is imaged mainly by lateral resolution and the borders are unclear.

TABLE III Correlation of Different Techniques for Measuring Cardiac Output*

Technique		Compared With	r	SEE	Slope	Intercept
Doppler CO	(Angio diameter)	CO invasive technique	0.94	0.46	0.86	0.31
Doppler CO	(Echo diameter)	CO Invasive technique	0.91	0.60	0.76	0.70
Doppler CO	(Angio diameter)	Doppler CO (echo diameter)	0.90	0.75	0.98	0.00
Doppler PO	(Angio diameter)	PO invasive	0.94	0.51	0.79	0.80
Doppler PO	(Echo diameter)	PO invasive	0.72	1.11	1.11	−0.23
Doppler PO	(Angio diameter)	Doppler PO (echo diameter)	0.70	0.75	0.378	2.28
Doppler P + S output	(Angio diameter)	P + S invasive	0.94	0.51	0.83	0.61
Doppler P + S output	(Echo diameter)	P + S invasive	0.79	0.95	0.87	0.50
Doppler P + S CO	(Echo diameter)	Doppler P + S CO (angio diameter)	0.75	0.94	0.62	1.21

* All correlation coefficients are positive and significant at $p < 0.001$. The correlation (r), standard error of the estimate (SEE), slope, and intercept for each relation are listed. For example, the first data is a comparison of (1) cardiac output by Doppler with vessel measurement by angiography, and (2) cardiac output measured invasively.

Note: These data show that echocardiographically measured pulmonary diameters produce lower correlation of Doppler and invasive cardiac outputs than do echocardiographically measured aortic diameters. angio = angiographic; echo = echocardiographic; CO = cardiac output; PO = pulmonary output; P + S = pulmonary plus systemic.

Measurements of the diameter on different frames of the same person varied by 3.8 mm. Such imprecision is a major problem, for the diameter divided by 2 must be raised to the second power to compute vessel area. This error in vessel size on echocardiography caused the low correlation (+0.72) of measured flow and Doppler flow. Furthermore, we studied the pulmonary size in children in whom better images are usually recorded than those in adults. A more accurate estimate of pulmonary artery size, obtained by angiography, improved the correlation to +0.94. Improved echocardiographic resolution may reduce this problem but will never solve it. Currently, an angiographic vessel measurement is necessary for very high correlation of pulmonary flow measured by pulsed Doppler and by invasive techniques. Obtaining pulmonary flow velocity was never a problem.

Problem of aortic flow velocity measurement: Aortic flow velocity measurement was not possible in 4 patients because the transducer was physically too large to place in the suprasternal notch. In several other patients, appropriate imaging was achieved only with hyperextension of the neck and considerable effort. Echocardiographic measurement of the diameter of the ascending aorta was not a problem, as borne out by the similarity of correlation for flow with an aniographic aortic measurement (+0.94) and an echocardiographic aortic measurement (+0.91).

All correlations were obtained over a large span of cardiac outputs in children ranging in age from 3 months to 17 years. The correlation might not be as good in a group of adults of uniform size.

Angular measurements: On the assumption that flow generally paralleled the ascending aortic walls, we determined the angle between the walls and the Doppler beam. This measurement proved to be easy and repeatable. Furthermore, if the intercept angle was within 20° of the flow axis, the error introduced by imprecise measurement would be small. Angular measurement could prove to be a significant problem if other echocardiographic planes, such as the subcostal, were used because the angle of the third, but unobserved, plane could be large.

Experience with fast Fourier transform: Spectral analysis by fast Fourier transform introduces a problem not encountered with time interval histography. With time interval histography, only the average frequency for a given time period is recorded. This characteristic makes time interval histography highly vulnerable to disturbed flow; consequently, the results of disturbed flow measurement will be very alinear.[11] Furthermore, with time interval histography, for any discrete time interval, frequency does not appear to have width. Fast Fourier analysis, however, allows display of all contained frequencies at each time interval. The analyzer used in this study depicted, for each time interval, the amplitude of the energy at each frequency as a shade of the gray scale, so that the highest recorded energies were more toward the black end of the scale and the lowest energies more toward the white. We elected to integrate the velocity curve by tracing the center of the darkest portion of the curve containing the most common frequency shift. This is a compromise. Merely averaging the spectrum for Doppler analysis would allow random turbulent velocities to be overemphasized. Tracing the center of the darkest part of the spectrum allows slight subjectivity, but interobserver variability on the same tracing was insignificant. The reasons that interobserver differences are so slight are (1) the technique is easy to apply, and (2) the mean integral is used in the computation. Use of the mean integral reduces minor interobserver tracing differences.

Comparison of results with those of other investigations: In this investigation, cardiac output determined by Doppler echocardiography and by invasive techniques demonstrated a better correlation than that reported by Magnin et al,[7] who also used a 2-dimensional sample volume locator. In their investigation, spectral analysis was performed by time interval histography. Their results showed a useful correlation ($r = +0.83$), but the slope of the regression line was 0.6x with a major offset (about 3.3 liters/min). By comparison, the fast Fourier transform used in this study to determine frequency shifts is essentially a linear system,[11] and this linearity probably permitted the better results presented in this study. Our results with visually directed placement of the Doppler sample volume approximate those of aortic outputs obtained with continuous wave Doppler,[1–3,5] but we regard as highly preferable the placement of a range-gated pulsed Doppler sample volume into a known vessel location defined by 2-dimensional echocardiography, because great vessels, particularly in patients with congenital cardiac disease, may occur in unexpected locations and have unusual courses. Furthermore, with continuous wave Doppler, the Doppler shift throughout the entire ultrasound beam is sampled and the result is a summation of all received Doppler signals. Accordingly, the sample may include additional and undesired atrial or ventricular velocities. With range-gated pulsed Doppler, velocity is sampled exclusively in the area of interest.

Flow profiles: In this investigation we assumed that the flow profile in or near the center of a large vessel was approximately flat, that is, that flow velocity was uniform across most of the vessel diameter. This was an important consideration, for if the flow profile had any other shape, positioning of the area sample volume would be critical, and unless the exact profile were known, the output could not be determined reliably from a single sample. A flat flow profile in large vessels is consistent with theory and results obtained by others.[12] In some patients mild to moderate flow disturbances were detected as a broadening of the spectral pattern. Under conditions of flow disturbance, the broadening of the curve observed with fast Fourier transform is markedly less than that observed with time interval histography.[13] In this study a recognizable and traceable forward flow velocity curve was still obtainable despite some flow disturbance in all but 1 instance. If frequency broadening obscured the forward flow

curve, no flow was computed. Results in those patients with mild flow disturbances, when compared with those of the invasive measures, were not different from results for the group as a whole.

Maximal velocities: The maximal velocity recorded in our patients did not exceed the maximal velocity for the given depth of interrogation; however, velocities exceeding the maximal detectable velocity do occur, particularly in patients with high flow or jets. The reason we did not encounter this problem is that we worked within 0 to 8 cm of the transducer. These close ranges will not be possible in all patients. Maximal velocity is limited mainly by the transmitted frequency and the pulse repetition frequency, the latter of which, in turn, is determined by the depth of the sample. Maximal velocity is usually expressed as the velocity on either side of zero; for example, ±110 cm/s measures a velocity span of 220 cm/s. It is currently unclear whether the span from 220 cm/s to zero is equivalent to ±110 cm/s. We did not utilize the total span on 1 side of zero in this study.

In conclusion, on the basis of our results, range-gated pulsed Doppler flow analysis using 2-dimensional echocardiography for sample volume location and intercept angle measurement and Fourier transform spectral analysis appears to provide clinically useful measurements of cardiac output if vessel diameter can be determined. However, numerous problems were encountered. Continued technical research into smaller transducer configurations, which might be useful in the suprasternal notch, and into techniques for improving imaging of the pulmonary artery should allow reliable, accurate measurements of great vessel blood flows.

The Isovolumic Index: A New Noninvasive Approach to the Assessment of Left Ventricular Function in Man

G. B. JOHN MANCINI, MD, FRCP(C), DENNIS COSTELLO, MD, VALMIK BHARGAVA, PhD, WILBUR LEW, MD, MARTIN LeWINTER, MD, and JOEL S. KARLINER, MD

Both a high ratio of preejection period (PEP) to left ventricular ejection time (LVET) and a prolonged isovolumic relaxation time are associated with left ventricular dysfunction. In pilot studies in instrumented dogs, we measured a combined isovolumic index, defined as (isovolumic contraction + isovolumic relaxation time)/LVET and found an inverse correlation with changes in fractional shortening. To test the utility of this index in human subjects, we used the electrocardiogram, mitral valve (MV) echogram, and indirect carotid arterial tracing to calculate isovolumic index as (time from R wave to MV opening − LVET)/LVET × 100%. Normal subjects had isovolumic index values that averaged 24 ± 7% (standard deviation), in contrast to patients with cardiomyopathy who averaged 65 ± 14% ($p < 0.001$ versus normal values) and patients with coronary artery disease who averaged 40 ± 15% ($p < 0.001$ versus normal values and patients with cardiomyopathy). All normal subjects had an isovolumic index of ≤32% and all patients with cardiomyopathy had values >32%. Of patients with coronary artery disease, 72% (21 of 29) had an isovolumic index >32%. An isovolumic index >32% identified 20 of 22 patients (91%) with a reduced ejection fraction and 12 of 14 (86%) with a segmental wall motion abnormality, and it was a more sensitive marker of these abnormalities than abnormal E point-septal separation. In 6 patients with coronary artery disease who had simultaneous echocardiograms and measurements of left ventricular pressure by micromanometer tip catheter, the time constants of isovolumic pressure decrease were uniformly increased in association with an isovolumic index >32%. In contrast, all had normal PEP/LVET ratios. The isovolumic index is thus a sensitive, potentially useful noninvasive marker of left ventricular dysfunction that is easily obtained from the routine echocardiogram.

It has long been appreciated that in patients with left ventricular myocardial disease the period of isovolumic contraction is often lengthened whereas the ejection time is diminished.[1-3] When the preejection period is used as an estimate of the isovolumic contraction time, the ratio of preejection period to left ventricular ejection time can provide a useful index of abnormal left ventricular performance which has been correlated inversely with cardiac output, stroke volume, and fractional shortening.[2,4] More recently a number of studies have demonstrated that indexes of myocardial relaxation are frequently abnormal in patients with left ventricular myocardial disease.[5-14] We therefore postulated that a ratio of the sum of isovolumic contraction and relaxation times to left ventricular ejection time might be a sensitive index for the identification of left ventricular dysfunction. In pilot studies in dogs, described subsequently, this ratio did show an inverse correlation with fractional shortening. Accordingly, we then used a simple echocardiographic technique to derive the ratio and tested whether it would detect differences among a population of normal subjects, patients with coronary artery disease, and patients with congestive cardiomyopathy. We also assessed the sensitivity, specificity, and predictive accuracy of this ratio in detecting familiar markers of left ventricular dysfunction (wall motion disorder, depression of the ejection fraction, and abnormalities of myocardial relaxation) and compared the ratio to 2 other noninvasive indexes of left ventricular

dysfunction, echocardiographic E point-septal separation and the preejection period/left ventricular ejection time ratio (PEP/LVET).

Methods

Animal studies: Six adult mongrel dogs were anesthetized with intravenous morphine sulfate (3 mg/kg) and alpha chloralose (90 mg/kg). The dogs were intubated and respiration was maintained with a Harvard respirator. The heart was exposed through a median sternotomy and suspended in a pericardial cradle. Pacing electrodes were sutured to the left atrium, and propranolol (1 mg/kg) was administered intravenously. Fluid-filled catheters were placed in the left atrium through a pulmonary vein and in the left ventricle through a femoral artery. These catheters were connected to Statham P23Db transducers with zero reference at the level of the right atrium. A Konigsberg P20 micromanometer was then inserted through the left atrial appendage into the left ventricle. The pressure obtained from the micromanometer was matched to that from the fluid-filled catheter. The latter was then withdrawn to a position just above the aortic valve to provide a recording of central aortic pressure. The micromanometer was frequently checked for drift by comparing peak left ventricular systolic pressure to peak aortic pressure. An inflatable occlusion cuff was then placed about the inferior vena cava. Finally, a pair of 5 MHz piezoelectric crystals (1.5 mm in diameter) were inserted through stab wounds in the left ventricular myocardium to the mid-wall depth approximately 1 cm apart. The crystals were placed at the midpoint, perpendicular to the ventricular long axis, and connected to a sonomicrometer-amplifier system for measurement of the shortening of a segment of myocardium oriented with the hoop axis fibers. The sonomicrometer was calibrated with a signal of known delay after the completion of each study. Atrial pacing at rates of approximately 10 beats/min greater than the basal rate was then initiated to maintain heart rate constant during the rest of the experimental protocol. To vary left ventricular preload and fractional shortening, the caval occlusion cuff was first inflated until end-diastolic pressure was 5 mm Hg or less. The cuff was then deflated in small increments with a data point obtained after each deflation. Once the cuff was completely deflated, an intravenous infusion of dextran in saline solution was begun to increase end-diastolic pressure to the 15 to 20 mm Hg range. Data were obtained at 3 to 7 points as left ventricular end-diastolic pressure was increased to this level.

All data were recorded on a polygraph (Brush Clevite, model 2000) and analyzed at a paper speed of 200 mm/s with respiration suspended at end-expiration. Five cardiac cycles were averaged for each measurement.

Four discrete timing events were measured. Left ventricular end-diastole was defined as the nadir of the pressure tracing after the *a* wave of the high gain left ventricular pressure tracing. Aortic valve opening and closure were defined by the aortic pressure recordings from the upstroke and dicrotic notch and transposed to the micromanometer tracing. Mitral valve opening was determined by the pressure cross-over points of the left atrial and left ventricular pressures. Fractional segment shortening was calculated as the difference between segment length at aortic valve opening and closure divided by segment length at aortic valve opening.

The isovolumic index (IVI) in these animals was defined as the sum of the duration of isovolumic contraction (IVC, from end-diastole to aortic valve opening) and isovolumic relaxation (IVR, from aortic valve closure to mitral valve opening) divided by the left ventricular ejection time (LVET) and expressed as a percentage: IVI (%) = [(IVC + IVR)/LVET] × 100.

Clinical studies: *Patient population:* The normal group consisted of 14 subjects; 6 were volunteers, 7 had been referred for the evaluation of innocent murmurs, and 1 had an echocardiogram performed before cardiac catheterization for the evaluation of atypical chest pain. Catheterization subsequently revealed no hemodynamic, left ventricular, or coronary angiographic abnormalities. All subjects had normal results on physical examination. None was taking any medication at the time of study and all had normal M-mode and 2-dimensional echocardiographic examinations. The mean age of this group was 31 ± 13 (SD) years (range 17 to 61). Resting heart rates ranged between 51 and 90 beats/min (mean 66 ± 10) and the blood pressure was 120/77 ± 18/9 mm Hg.

The cardiomyopathy group included 12 patients ranging in age from 34 to 70 years (mean 54 ± 10). All had dilated forms of cardiomyopathy with chronic, stable symptoms of congestive heart failure. The cause was ischemic in 10 and idiopathic in 2. One patient was not receiving medication at the time of the study. All others were taking digoxin and diuretics. Six of the 12 were receiving prazosin, 3 were ingesting nitrates, and 1 was also taking hydralazine. Two patients were receiving concomitant oral amrinone therapy. All 12 patients were in sinus rhythm with rates ranging between 58 and 99 beats/min (mean 79 ± 14), while the blood pressure was 113/72 ± 14/13 mm Hg. No patient had clinical evidence of valvular disease. Resting equilibrium radionuclide angiography was performed in all of these patients for measurement of ejection fraction.

The group with coronary artery disease included 29 patients, of whom 8 had undergone diagnostic cardiac catheterization within 2 weeks of the echocardiographic study. Seven patients were studied within 48 hours of catheterization, and 6 patients underwent echocardiography at the time of cardiac catheterization. All 21 catheterized patients had evidence of significant coronary artery disease as defined by angiographic luminal narrowing of 70% or more in at least 1 major vessel. The other 8 patients with coronary artery disease had either a history of a myocardial infarction (as evidenced by a typical history, diagnostic changes in creatine kinase levels, and evolution of persistent electrocardiographic signs) or a history of chronic, stable angina with diagnostic electrocardiographic or reversible thallium-201 scintigraphic abnormalities, or both, during exercise. Six of these 8 patients also had resting gated radionuclide ejection fraction determinations. Echocardiographic and radionuclide examinations were carried out at least 6 months after acute infarction in this group, and in all cases ischemic symptoms were stable. One patient with coronary artery disease was receiving digoxin at the time of study and 18 were taking beta-blocking drugs. Ages ranged from 24 to 69 years (mean 53 ± 12). During echocardiographic study the blood pressure was 131/79 ± 27/16 mm Hg and the heart rate was 66 ± 13 beats/min (range 46 to 90). No patient had evidence of valvular disease.

The 3 groups were not different with respect to blood pressure, but both groups of patients had a higher mean age than that of normal subjects ($p < 0.001$) and the mean heart rate in the cardiomyopathy group was higher than that in the other two groups ($p < 0.025$).

Methods: All patients underwent M-mode echocardiography using a Toshiba SSH-10A sonolayergraph with a Toshiba strip chart recorder. Each normal patient and all patients with cardiomyopathy also had 2-dimensional echocardiographic

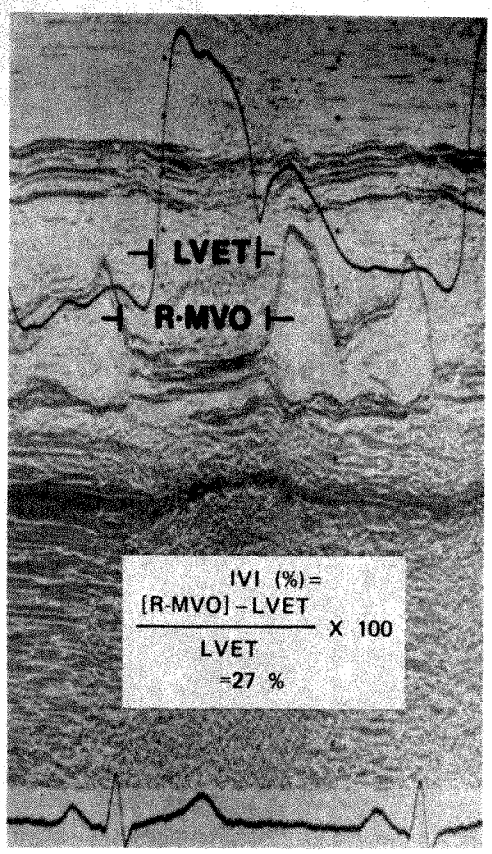

FIGURE 1. Calculation of the isovolumic index (IVI) from the simultaneous carotid arterial pulse tracing and mitral valve echocardiogram is demonstrated in a normal patient. LVET = left ventricular ejection time; R-MVO = the time from the peak of the R wave to mitral valve opening. **Dotted time markers** are at intervals of 500 ms.

examination using a 78° electronic phased array transducer to exclude unsuspected segmental wall motion abnormalities or valvular disease such as mitral valve prolapse. Simultaneous carotid arterial pulse tracings were recorded using a Fukuda model TY-303 transducer.

In the 6 patients with coronary artery disease who had echocardiographic examinations during cardiac catheterization, simultaneous left ventricular pressure was measured with a micromanometer tip high-fidelity catheter (Millar). Pressures were acquired on-line onto computer tape. Left ventricular pressure was also displayed on the echocardiographic strip chart paper and by using calibration signals, the specific high fidelity pressure tracing corresponding to simultaneous echocardiography events could be identified. This approach eliminated the need to hand-digitize the left ventricular pressure recording from high speed recordings so that the Toshiba strip chart recorder could be run at 50 mm/s. At this speed the mitral valve echocardiogram was not excessively expanded.

The mitral valve echocardiogram was obtained with the transducer in the second to fifth intercostal spaces and within 3 to 4 cm of the left sternal border such that maximal excursion of the mitral valve leaflets was recorded. The onset of mitral valve opening was taken from the onset of the most rapid anterior motion of the anterior mitral valve leaflet[15] (Fig. 1).

A suitable limb electrocardiographic lead was selected which showed a sharp R wave and this was recorded simultaneously on the strip chart. No patient had evidence of bundle branch block.

The isovolumic index was determined as follows. The left ventricular ejection time was taken from the onset of the most rapid upstroke of the catorid arterial pulse tracing to the dicrotic notch. The period from the peak of the R wave to the mitral valve opening (R-MVO) was then determined. We chose the peak of the R wave from which to measure the interval of total electromechanical systole and isovolumic relaxation (R-MVO) because in our experience it was more easily reproducible than the onset of the Q wave, particularly in tracings recorded from the echocardiographic strip chart, in which gain and lead selection are limited. Subtracting left ventricular ejection time from R-MVO gives an interval that includes isovolumic contraction, isovolumic relaxation, and a small interval of electromechanical delay. Therefore, this measure provides an estimation of the time during which the left ventricle is in an isovolumic state and is termed the *isovolumic time* (IVT). Thus, the echocardiographic isovolumic index was defined as follows: IVI (%) = [(R-MVO − LVET)/LVET] × 100 = (IVT/LVET) × 100.

Recordings were made during quiet respiration and 5 suitable cycles were averaged to determine the isovolumic index. Because we did not calculate the delay in the carotid pulse tracing, the actual preejection period (time for electromechanical delay plus isovolumic contraction) and the precise duration of isovolumic relaxation could not be determined separately by this method.

The E point-septal separation was determined in all suitable M-mode recordings (51 of 55 patients) and considered abnormal when ≥5.5 mm.[16] PEP/LVET was calculated from the simultaneous electrocardiogram and micromanometer ascending aortic pressure tracing in the 6 patients studied at the time of catheterization.[17] The preejection period was measured from the onset of the Q wave to the onset of the most rapid upstroke of the ascending aortic pressure tracing. In 7 of the 12 patients with cardiomyopathy PEP/LVET was determined noninvasively in standard fashion[1–3] on the same day as the echocardiographic study.

High fidelity left ventricular pressure tracings were digitized at 200 samples/s and the first derivative of the left ventricular pressure was computed. End-diastolic pressure was defined as the pressure at which dP/dt reached 200 mm Hg/s and the pressure increased monotonically thereafter. The interval of isovolumic relaxation was defined from the time of peak negative dP/dt to a point at which the left ventricular pressure was at least 10 mm Hg above end-diastolic pressure of that beat. Left ventricular isovolumic pressure (P) with respect to time (t) was then fitted to an exponential curve[18] of the form: $P = P_0 \exp(-t/T)$, where P_0 is the pressure at peak negative dP/dt and T is the time constant. In each patient T was measured from the same 5 beats from which the isovolumic index was calculated. T_1[10] was calculated in the same fashion using only the first 40 ms of the isovolumic pressure decline.

Biplane left ventricular cineangiograms were examined independently by 2 observers without knowledge of the isovolumic index for identification of areas of hypokinesia, akinesia, or dyskinesia.

Gated equilibrium radionuclide angiograms at rest were obtained by a protocol validated in our laboratory and described previously.[19] The difference in counts/cycle in studies repeated at least 1 month apart was ±1% and the interobserver variation was also ±1% counts/cycle. The radionuclide ejection

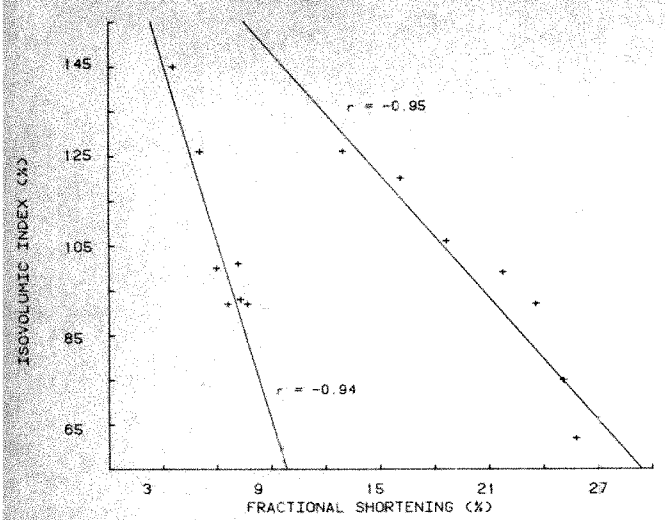

FIGURE 2. Correlation between fractional shortening and isovolumic index is demonstrated in 2 dogs.

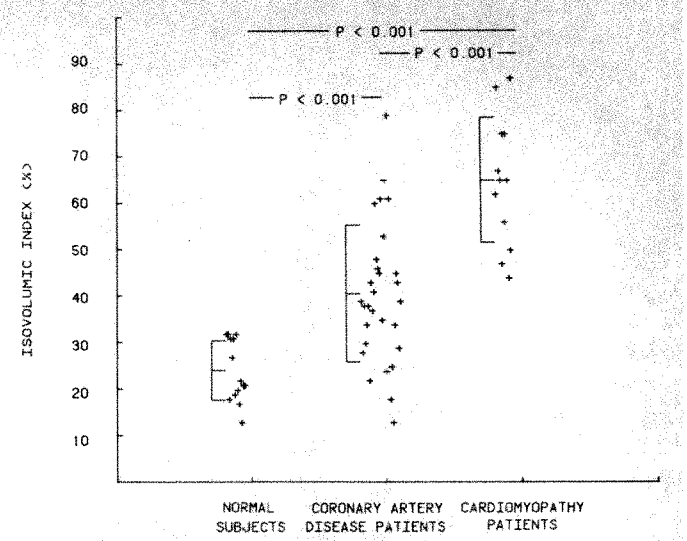

FIGURE 3. Isovolumic index in the study population. Means ± 1 standard deviation are shown.

fraction was determined without knowledge of the isovolumic index.

Statistics: All data are given as mean ± 1 standard deviation. The chi-square test with Yate's correction and the paired and unpaired Student's *t* tests were used when appropriate to assess statistical significance. Correlations were tested using linear regression analysis.

"Sensitivity" was defined as the number of true-positive test results divided by the total number of subjects with the clinical abnormality being analyzed. "Specificity" was defined as the number of true-negative test results divided by the total number of subjects without the clinical abnormality being analyzed. "Predictive accuracy" was defined as the number of true-positive test results divided by the total number of positive test results.

Results

Animal studies: Figure 2 demonstrates the correlations in 2 dogs between the isovolumic index and fractional shortening during 7 stepwise increases in the left ventricular filling pressure. Note that the isovolumic index decreased as fractional shortening improved. In 3 of the remaining 4 dogs, the correlations were also high ($r = -0.94$, -0.97, and -0.99), whereas the last correlation was -0.75.

Clinical studies: The isovolumic index did not correlate significantly with age, heart rate, systolic blood pressure, or mean blood pressure. As shown in Figure 3, normal subjects had the lowest isovolumic index (24 ± 7%) in contrast to patients with cardiomyopathy (65 ± 14%, $p < 0.001$ versus normal subjects) and those with coronary artery disease (40 ± 15%, $p < 0.001$ versus normal subjects and patients with cardiomyopathy).

All normal patients had an isovolumic index ≤32% whereas all patients with cardiomyopathy had values >32%. The coronary group showed some overlap with the normal subjects, but the majority (21 of 29, 72%) had an isovolumic index >32%.

Analysis of the coronary patients alone (Table I) showed no significant difference in the absolute value of the IVI in those who (1) were or were not taking beta-blocking drugs, (2) did or did not have a wall motion abnormality, (3) had a normal or reduced ejection fraction, and (4) had an elevated or normal left ventricular end-diastolic pressure.

Table II demonstrates the sensitivity, specificity, and predictive accuracy of an elevated isovolumic index (>32%) and an abnormal E point-septal separation (≥5.5 mm)[16] for (1) the presence of disease in the entire study group; (2) the presence of coronary disease (excluding coronary patients in the cardiomyopathy group); (3) the presence of wall motion abnormalities whether segmental or diffuse (including patients with cardiomyopathy); and (4) the presence of an abnormal ejection fraction. A radionuclide ejection fraction <50% or an angiographic ejection fraction <55% was consid-

TABLE I Subclassification of Patients With Coronary Artery Disease

Class	Patient Data	Isovolumic Index (%)	
I	On beta-blocking drugs (n = 18)	44 ± 15	
			p = NS
	Off beta-blocking drugs (n = 11)	35 ± 12	
II	Wall motion abnormality (n = 14)	43 ± 11	
			p = NS
	No wall motion abnormality (n = 7)	46 ± 19	
III	Subnormal ejection fraction (n = 10)	42 ± 12	
			p = NS
	Normal ejection fraction (n = 17)	40 ± 17	
IV	Left ventricular end-diastolic pressure >12 mm Hg (n = 9)	41 ± 11	
			p = NS
	Left ventricular end-diastolic pressure ≤12 mm Hg (n = 12)	47 ± 16	

ered abnormal. Note that the isovolumic index was a more sensitive indicator than an abnormal E point-septal separation for the presence of these commonly employed markers of left ventricular dysfunction. However, the specificity and predictive accuracy tended to be lower. Because the E point-septal separation was always normal when the isovolumic index was normal whereas the isovolumic index was sometimes increased despite a normal E point-septal separation, it follows that the sensitivity, specificity, and predictive accuracy of the presence of abnormalities of either of these measures or both merely reflected the behavior of the isovolumic index alone.

For purposes of comparison with E point-septal separation, an abnormal isovolumic index was defined as any value greater than the highest found in our normal group (that is, 32%), because this is the way an abnormal E point-septal separation has been defined previously.[16] Using >38% (2 standard deviations above the normal group mean) as the definition of an abnormal isovolumic index, the sensitivity decreased modestly. However, sensitivity improved when either or both of these measures were abnormal (Table III).

Simultaneous hemodynamic and echocardiographic data from the 6 coronary patients so studied are shown in Table IV. All patients had significant wall motion abnormalities. Despite the occurrence of both normal and abnormal ejection fractions and end-diastolic pressures and the wide range of peak positive and negative dP/dt values, all patients had abnormal time constants of relaxation.[9,10] Note that the isovolumic index was >38% in 5 of the 6 and >32% in all, whereas all had a normal PEP/LVET (<0.42).[20,21] In contrast, in the 7 patients with cardiomyopathy in whom these determinations were made, both PEP/LVET and the isovolumic index were abnormal.

As indicated, the PEP/LVET and the isovolumic index could be compared in a total of 13 patients (6 with coronary artery disease and 7 with cardiomyopathy). In this subgroup, the PEP/LVET (expressed as a percentage) averaged 45 ± 14 and was invariably smaller than the isovolumic index, which averaged 60 ± 17 ($p < 0.01$).

In a random subgroup of 10 patients the isovolumic index as measured independently by 2 observers varied by ±8%. In a separate subgroup of 7 subjects, the re-

TABLE II Sensitivity, Specificity, and Predictive Accuracy of an Increased Isovolumic Index (↑IVI) or Abnormal E Point-Septal Separation (↑EPSS) for the Presence of Disease and Left Ventricular Dysfunction

IVI = isovolumic index; LVEDP = left ventricular end-diastolic pressure; LVET = left ventricular ejection time; PEP = preejection period.

producibility of the measurement from 2 different echocardiograms performed on 2 separate occasions (at least 24 hours apart) when there had been no interval change in clinical status or drug therapy was ±5%.

Discussion

The isovolumic index as we have defined it is an easily obtainable echocardiographic measurement that requires only the recording of an electrocardiographic R wave, a carotid arterial pulse tracing, and the echocardiogram of the anterior leaflet of the mitral valve. These recordings are well within the capabilities of any echocardiographic laboratory and do not require special equipment or a change in the usual routine of echocardiographic examination. Furthermore, the noninvasive nature of this procedure lends itself to widespread application and repeated measurements over the course of a patient's illness or perhaps during interventions and specific therapy.

Although the use of single-channel dual echocardiography allows for the direct measurement of isovolumic contraction and relaxation,[22] it is often difficult to obtain consistent, clear, simultaneous echograms of aortic and mitral valve opening and closure, and it is virtually impossible with only 1 operator. The isovolumic index can be recorded in virtually any patient and without the need for split-screen capabilities or added personnel.

The rationale for this measurement stems from 2 lines of reasoning. First, abnormalities of left ventricular relaxation have been noted in patients with coronary artery disease even in the absence of wall motion abnormalities, subnormal values for ejection fraction at rest, or acute ischemia.[5–7,9,10] These abnormalities have been detected by measurement of peak negative dP/dt or the time constant or isovolumic pressure decrease using invasive techniques, or both. Although the isovolumic index gives no information about the rate of pressure decrease during relaxation, an abnormally slow rate of decline can obviously influence the isovolumic index by increasing the total isovolumic period. Indeed, others have shown that the isovolumic relaxation period as measured echocardiographically or by apexcardiography is prolonged at rest in many patients with coronary artery disease when compared with normal subjects.[11–14,23]

The second line of reasoning providing a rationale for measurement of the isovolumic index stems from previous work describing systolic time intervals. Initial observations demonstrated that nonvalvular heart disease tended to lengthen the preejection period while the ejection time became shortened. The PEP/LVET ratio provided a useful index which correlated with cardiac output and stroke volume.[1–3] Others showed similar correlations of PEP/LVET with fractional shortening.[4] Stack et al[21,24] demonstrated its apparent utility in coronary disease. In addition, Lewis et al[25] demonstrated that the PEP/LVET ratio was somewhat sensitive to the presence of wall motion abnormalities in patients with coronary disease. Although their patients with wall motion disorders had statistically lower angiographic ejection fractions than did those without segmental abnormalities, the average ejection fraction in both groups remained normal. Even so, PEP/LVET was significantly greater in the presence of segmental contraction disorders.

On the basis of these observations, we hypothesized that an index combining isovolumic contraction, relaxation, and left ventricular ejection times might be a sensitive marker for the presence of cardiac disease. We also anticipated that abnormalities in such an index might occur in the absence of commonly accepted indicators of left ventricular dysfunction, because abnormalities in the components of this index have been noted even without the presence of wall motion abnormalities or a depressed ejection fraction. The results shown in Table II appear to bear out these predictions. Thus, the isovolumic index is a sensitive indicator of the presence of disease even in the absence of wall motion abnormalities or a depressed ejection fraction, or both, and it is more sensitive than increased E point-septal separation in this regard. Perhaps not surprisingly, the specificity and predictive accuracy of the isovolumic index for the presence of these abnormalities are less impressive than its sensitivity. This finding could reflect the possibility that very subtle aberrations of the relation between isovolumic contraction and relaxation and ejection may result from the presence of coronary artery

disease even when the disease is uncomplicated by abnormalities of left ventricular function detected by other techniques. The use of a higher value to define an abnormal isovolumic index (>38%) enhanced specificity. Furthermore, the sensitivities of the isovolumic index and abnormal E point-septal separation were each improved when either or both of these abnormalities were present (Table III). Although the isovolumic index is highly sensitive and compares favorably with E point-septal separation, the overlap between patients with coronary artery disease and normal subjects (Fig. 3) demonstrates that it does not completely identify all such patients. As indicated previously, although patients with coronary disease may have abnormalities of the components of the isovolumic index without other indicators of abnormal ventricular function, it is not always the case. Hence, some degree of overlap is to be anticipated, and like all other noninvasive indexes, the isovolumic index is not completely sensitive in this regard.

Although we initially hoped that the isovolumic index would correlate in a linear fashion with ejection fraction in the entire clinical population as it did with fractional shortening in the experimental animals, this did not turn out to be the case. Similar problems have been noted by some with respect to the use of PEP/LVET or E point-septal separation for the prediction of ejection fraction in coronary patients.[16,26–28] Nevertheless, our experimental preparation demonstrated a high negative correlation of the isovolumic index with improved fractional shortening when each dog was considered individually. This finding underscores 2 points. First, as the animal studies demonstrate, the isovolumic index may be influenced by differences in loading conditions, variables that were not manipulated in our clinical population and that require further investigation. Second, although we showed the usefulness of an isolated determination of the isovolumic index in the clinical subjects the animal data suggest that serial measurements in an individual during changes in clinical status or therapy or during acute interventions may also be a useful application.

Although modest, age-dependent prolongation of systolic time intervals and relaxation have been observed,[9,23,29] others have failed to confirm this finding.[13] We found no age-dependence of the isovolumic index either in the entire study group or within each group. Similarly, the isovolumic index did not appear to be related to heart rate within the range of our study (46 to 99 beats/min), although it might vary as a function of heart rate in individual subjects.

This study does not specifically compare the isovolumic index with PEP/LVET as a predictor of coronary disease, wall motion abnormalities, or reduced ejection fraction. However, although PEP/LVET was calculated in only a minority of our coronary patients, it is of note that in each of these cases the isovolumic index was abnormal despite the presence of a normal PEP/LVET. This finding is consistent with the work of several other investigators who have demonstrated that PEP/LVET is not always sensitive in patients with coronary disease and left ventricular dysfunction.[26–28]

It is important to stress certain methodologic features of measurement of the isovolumic index, particularly as they relate to comparisons between the isovolumic index and routinely obtained PEP/LVET ratios. We chose the peak of the R wave from which to measure the interval of total electromechanical systole and isovolumic relaxation (R-MVO) because in our experience it is more easily reproducible than the onset of the Q wave, particularly in tracings recorded on the echocardiographic strip chart. As a consequence, a substantial portion of the true electromechanical delay is not included in the R-MVO interval. In subjects with a normal PEP/LVET, the time for electromechanical delay accounts for a much greater portion of the PEP/LVET ratio than it does in individuals with an increased PEP/LVET, assuming a QRS complex of normal duration. This disproportionate contribution of electromechanical delay in normal compared with abnormal subjects is further exaggerated in determining the isovolumic index because of the addition in the numerator of the isovolumic relaxation time, which is also shorter in normal subjects. The standard technique for measuring PEP/LVET employs the onset of the Q wave as the beginning of PEP. If PEP/LVET were defined from the peak of the R wave, however, values for PEP/LVET in normal subjects would be systematically much shorter than those calculated in the usual fashion. This explains the fact that our isovolumic index value of 24 ± 7% in normal subjects apears surprisingly small in comparison with standard PEP/LVET ratios. Furthermore, in the abnormal subjects in whom PEP/LVET and the isovolumic index could be compared, the index was appropriately longer than PEP/LVET, as would be anticipated in a group in which electromechanical delay is a less important determinant of both ratios. Moreover, methodologic differences in the recording of timing intervals can also produce substantially different results.[3,15,21,23] It is therefore important to employ strict methodologic techniques in calculating the isovolumic index, particularly in timing the beginning of electromechanical systole and mitral valve opening.

We conclude that the isovolumic index is a sensitive indicator of left ventricular dysfunction and of the presence of coronary disease in some patients without abnormalities of other measures of systolic function. Furthermore, because the isovolumic index is easily determined during routine echocardiography, it may also be useful in serial measurements in individual patients during various phases of disease or therapy, an application that will require future validation.

Laragh's eagerly awaited new guide to understanding, diagnosing, and treating Hypertension *in its many forms...*

TOPICS IN HYPERTENSION

Edited by JOHN H. LARAGH, MD

Master Professor of Medicine, Chief, Cardiology Division
Director, The Cardiovascular Center
The New York Hospital-Cornell Medical Center

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice . . . and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions by 85 eminent specialists. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

The book is conveniently organized for effective consultation and reading.

Important Information — Sequicor, Models 233D and 233E

Indications and Contraindications

The medical literature describes currently accepted indications for various pacing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs. *The physician should be thoroughly familiar with the pacing mode chosen.*

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing is contraindicated when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VDD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus mode dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation. VVI mode is recommended for these conditions.

Precautions

Cordis Sequicor pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Omnicor Programmer, Model 222C (with the 222C-8 control panel card), the Cordis Programmer III, Model 225A or the Cordis Interactive Programmer, Model 256A for reprogramming.

Warnings

None

Adverse Effects

The following list includes a number of complications related to pacer therapy that have been reported in the medical literature. Noninvasive techniques for assessing and managing such complications are available to the physician. Malfunctions occur randomly and may occur at any time after implant. Complications associated with pacer therapy are listed below.

Pacer — battery depletion, component malfunction, electromagnetic interference, decreased sensitivity.

Lead — unsatisfactory electrode position, fracture, displacement, penetration/perforation of heart wall, faulty connection with pacer.

Patient — reaction, infection/erosion, increase in stimulation threshold.

Before implantation, refer to pacer Instructions for Use supplied with the pacer.

Caution: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

SLOW-K® potassium chloride slow-release tablets

DESCRIPTION

Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS

BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS

In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (eg, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS

Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (eg, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS

Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS

Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION

Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

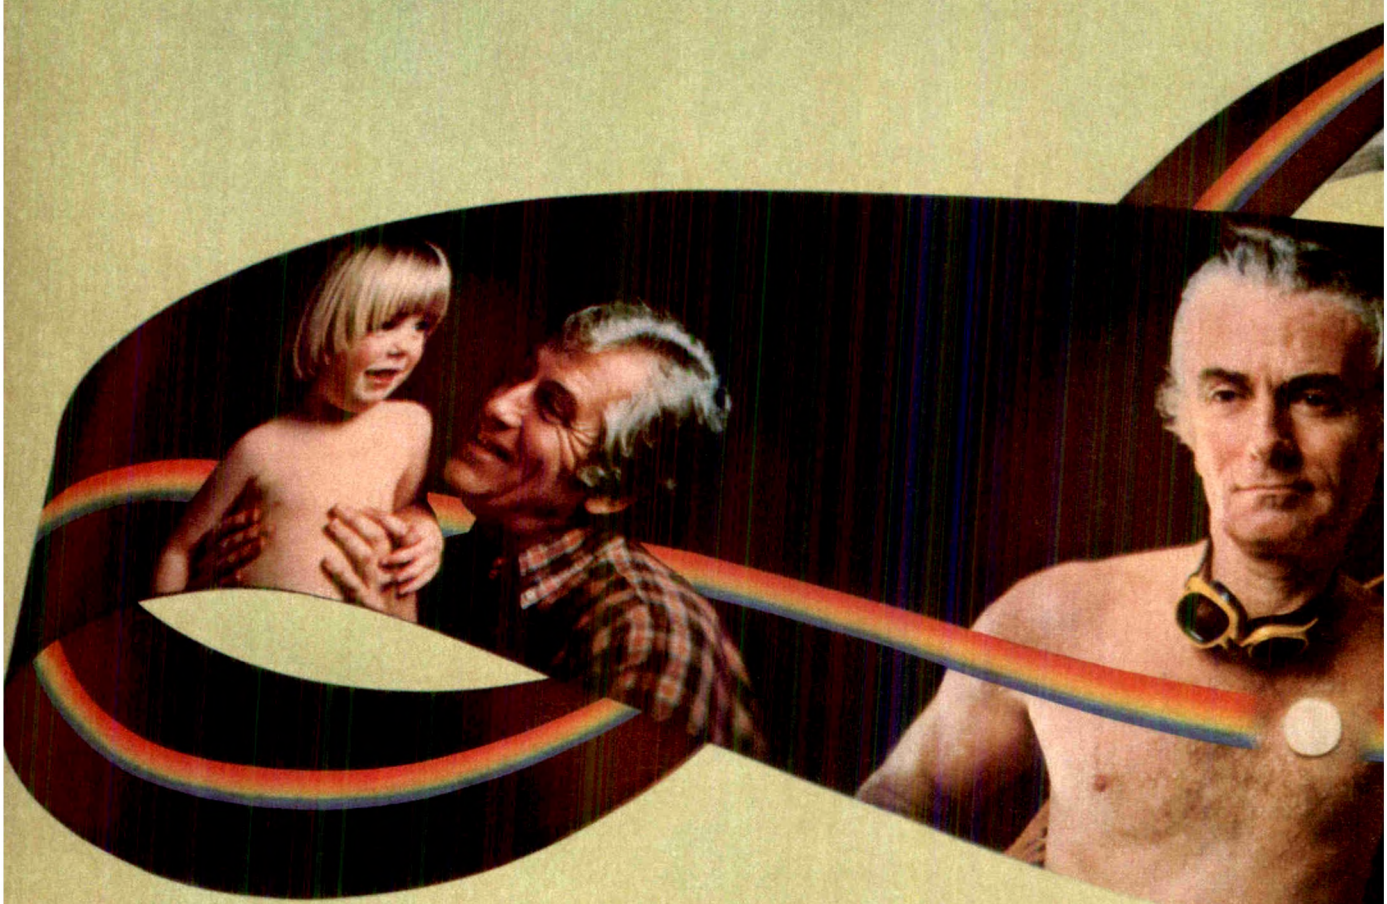
NITRODISC

(nitroglycerin) 5-MG/24-HR; 10-MG/24-HR PAD

Continuous anginal



Contraindications for nitroglycerin include patients with increased intraocular pressure. Side effects include headache, hypotension, flushing, and dizziness. In terminating treatment, both the dosage and frequency of application must be gradually reduced during a period of four to six weeks.

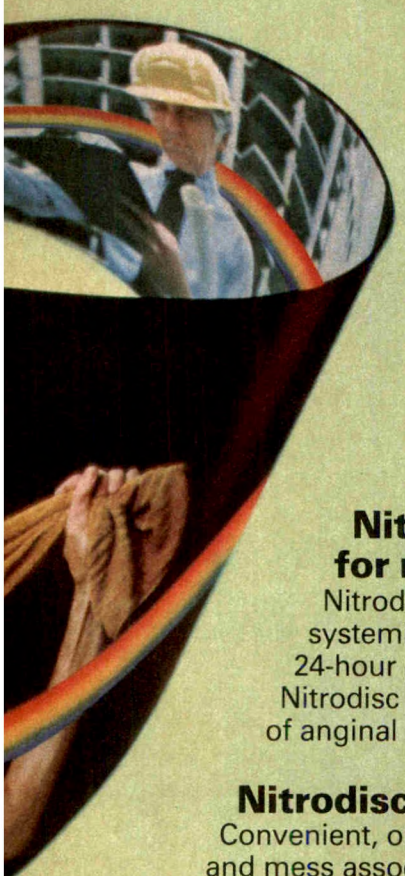
protection...q.d.

Preliminary results from a clinical study indicate 24-hour improvement in exercise capacity

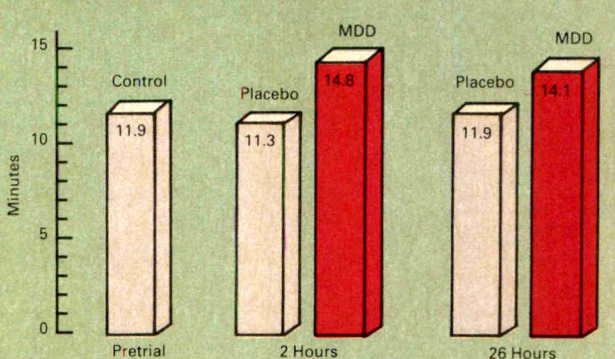
Until now, the clinically recognized benefits of a single nitrate dose have not been documented beyond 12 hours.

In a controlled study,[1] Searle's new nitroglycerin Microseal Drug Delivery™ (MDD) system provided an 18% average increase in exercise capacity 26 hours after application.[2]

In addition, the need for sublingual nitroglycerin was reduced.



Mean Exercise Duration



Nitrodisc (nitroglycerin) eliminates the need for multiple doses of long-acting oral nitrates

Nitrodisc's unique solid polymer releases nitroglycerin into the systemic circulation at a controlled and sustained rate over a 24-hour period.

Nitrodisc (nitroglycerin) is not intended for the immediate relief of anginal attacks.

Nitrodisc enhances compliance

Convenient, once-daily dosage schedule, plus the absence of bother and mess associated with nitroglycerin ointments.

Secure, waterproof adhesive allows for a complete range of daily activities.

1 The interim results presented include data on eight patients completing the protocol to date. A total of twenty patients will be included.

2 Thompson RH: Clinical use of transdermal delivery devices with nitroglycerin. Presented at the Medical Therapy for Angina in the 1980s: New Horizons Symposium, Atlanta, April 24, 1982.

In another clinical study conducted among cardiac rehabilitation participants, concomitant Nitrodisc (nitroglycerin) propranolol therapy did not demonstrate a significant improvement over propranolol alone.

Please see the following page for the complete prescribing information.

SEARLE

5-MG/24-HR; 10-MG/24-HR

NITRODISC™

(nitroglycerin)

DESCRIPTION: The Nitrodisc pad incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths that release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface (see HOW SUPPLIED section).

ACTIONS: When a Nitrodisc pad is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart and peripheral vasculature) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is due to a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In addition, a direct effect of nitroglycerin on the coronary vessels is recognized as well.

In clinical studies, transdermal absorption of nitroglycerin from Nitrodisc occurred in a continuous and well-controlled manner for a minimum of 24 hours. Therapeutic plasma levels were attained within 1 hour after the application of the pad and remained in the therapeutic range for 24 hours. Plasma levels of nitroglycerin were still detectable 30 minutes after removal of the system.

The amount of nitroglycerin released (5 mg/24 hr or 10 mg/24 hr) represents the mean absorption rates through skin determined during clinical evaluations. Absorption may vary among individuals.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: A Nitrodisc pad should be applied once each day. To use the pad, follow the instructions on the package. Nitrodisc should be applied to a skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new pad should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller pad, and that the larger pad be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

PATIENT INSTRUCTIONS FOR APPLICATION: These are provided with the product.

HOW SUPPLIED:

Nitrodisc	5 mg/24 hr	10 mg/24 hr
Drug released per 24 hours	5 mg	10 mg
Total drug content	16 mg	32 mg
Drug releasing surface	8 cm^2	16 cm^2

Nitrodisc pads are supplied in cartons of 30. Store at a controlled room temperature of 59°-86°F (15°-30°C). **Do not refrigerate.** Extremes of temperature and humidity should be avoided.

Exercise-Induced Decrease in Flow Through Stenotic Coronary Arteries in the Dog

JEFFREY S. SCHWARTZ, MD, BRUCE TOCKMAN, BS, JAY N. COHN, MD, and ROBERT J. BACHE, MD

In the presence of a coronary stenosis, it is generally believed that exercise-induced ischemia is caused by an inadequate increase in coronary blood flow. This study was carried out to test the hypothesis that, in the presence of a critical coronary stenosis, exercise would result in a decrease in flow across the stenosis. Five dogs were chronically instrumented with a flow probe and a wire snare occluder on the circumflex coronary artery and with catheters in the left atrium, left ventricle, and aorta. Four dogs also had a catheter in the circumflex coronary artery distal to the occluder. Measurements were recorded with the animals resting quietly and then during moderate exercise.

In the absence of a stenosis, circumflex flow increased with exercise. In 13 experiments in which a severe stenosis was produced in the circumflex coronary artery, the changes from rest to exercise were as follows: heart rate from 102 ± 7 to 151 ± 12 beats/min ($p < 0.001$), mean aortic pressure from 103 ± 4 to 107 ± 3 mm Hg (difference not significant), distal circumflex pressure from 71 ± 5 to 36 ± 2 mm Hg ($p < 0.001$), the pressure gradient across the stenosis from 32 ± 4 to 71 ± 3 mm Hg ($p < 0.001$), stenosis resistance from 2.3 ± 0.7 to 13.9 ± 3.9 units ($p < 0.01$), and flow through the stenotic artery from 29 ± 4 to 10 ± 3 ml/min ($p < 0.001$). Left ventricular filling pressure increased from 9 ± 1 to 15 ± 1 mm Hg ($p < 0.01$). The decrease in intraluminal pressure distal to the stenosis and thus in the stenosis itself may have resulted in passive narrowing of the stenotic segment, which may have caused the decrease in flow. Exercise, therefore, may result in a decrease in flow through a stenotic coronary artery.

It is generally believed that in patients with occlusive coronary artery disease, exercise results in an attenuated increase in flow through stenotic coronary arteries. Ischemia consequently develops because flow cannot increase sufficiently to meet myocardial oxygen demands. In support of this concept, studies of exercise in the presence of experimental coronary stenoses have shown an increase in total flow through the stenotic artery although the increase in flow was less than that through normal arteries.[1]

From the Department of Medicine, Cardiovascular Division, University of Minnesota Medical School, Minneapolis, Minnesota. This study was supported by Young Investigator Research Award Grant HL-21298 and by Grant HL-20598 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, and by a Grant-in-Aid from the American Heart Association, Dallas, Texas, with funds contributed in part by the American Heart Association, Minnesota Affiliate, Minneapolis, Minnesota. Manuscript received April 13, 1982, accepted June 9, 1982.

Address for reprints: Jeffrey S. Schwartz, MD, Department of Medicine, Box 258, Mayo Memorial Building, University of Minnesota Hospitals, Minneapolis, Minnesota 55455.

Previous studies in open-chest dogs have shown that in the presence of a severe nonfixed coronary stenosis, vasodilation of the distal coronary bed caused by transient coronary occlusion,[2,3] injection of contrast medium,[2] or rapid ventricular pacing[4] was associated with an increase in stenosis resistance and a decrease in flow through the stenotic artery.

Exercise is also known to cause vasodilation of the distal coronary bed and might also be expected to result in a similar decrease in flow through a severely stenotic coronary artery. However, there are potentially important differences between exercise-induced distal bed dilation and the previously studied interventions which might affect flow through a stenotic artery. As opposed to transient coronary occlusion, injection of contrast medium, or rapid pacing, exercise may cause an increase in systemic arterial pressure and may alter autonomic tone. Furthermore, the previous studies were all acute preparations in anesthetized open-chest dogs while exercise studies would necessitate intact unanesthetized chronically instrumented dogs. Therefore, the present

study was done to evaluate the effect of exercise on blood flow through severely stenotic coronary arteries.

Methods

We studied 5 chronically instrumented dogs weighing from 22 to 31 kg (mean 26 ± 2). The dogs were anesthetized with pentobarbital (25 mg/kg) and a left thoracotomy was performed in the fourth intercostal space. Heparin-filled catheters were placed in the aorta by way of the internal thoracic artery and in the left atrium and the left ventricle. The proximal portion of the left circumflex coronary artery was dissected free and a 2.5 or 3.0 mm electromagnetic flow probe was placed around the artery. A snare occluder was placed distal to the flow probe on the circumflex coronary artery. This occluder consisted of a soft wire snare threaded through polyethylene tubing. We were careful to be certain that the snare was placed loosely around the artery during surgery and that it had minimal contact with the artery before the chest was closed. In this way we hoped to minimize the development of fibrosis in the area where the stenosis would later be produced. A catheter was placed into the circumflex artery distal to the snare for the measurement of distal coronary arterial pressure. This catheter consisted of a short section of silastic tubing with an internal diameter of 0.02 in cemented to a long section of silastic tubing with an internal diameter of 0.04 in. A guidewire was inserted into the tubing to make it more rigid and the narrower section of tubing was threaded through a small branch of the circumflex artery into the left circumflex artery. The guidewire was then removed and the catheter was filled with heparin. The ends of the catheters, the snare, and the flow probe tubing were tunneled into a subcutaneous pouch and the chest was closed.

The studies were performed 1 to 2 weeks after surgery when the animals had recovered. Under 2% lidocaine infiltration anesthesia, the ends of the catheters and occluder tubing were removed from the subcutaneous pouch. The pressure catheters were connected to P23ID pressure transducers that were attached to a nylon vest which the dog had been trained to wear. In 1 dog, the distal catheter did not function so that resistance could not be calculated. In another dog the left ventricular catheter did not function. In the latter dog, however, left atrial pressure was measured so that left ventricular filling pressure could be determined. The end of the wire snare occluder was attached to a machinist's micrometer so that precise adjustments of the severity of the stenosis could be made. The micrometer was also mounted on the side of the nylon vest. The end of the flow probe was connected to a Statham P2202 electromagnetic flow meter. Zero flow, obtained by transient complete occlusion of the appropriate coronary artery, was determined frequently during the course of each experiment.

When the pressure and flow systems were functioning properly, the animal was allowed to rest quietly while a stenosis was produced in the coronary artery by tightening the wire snare. The animal then performed exercise, consisting of walking rapidly about the laboratory. Pressure and flow measurements were recorded during exercise. If exercise resulted in an increase in flow through the stenotic artery, the dog was again allowed to rest quietly while the snare was

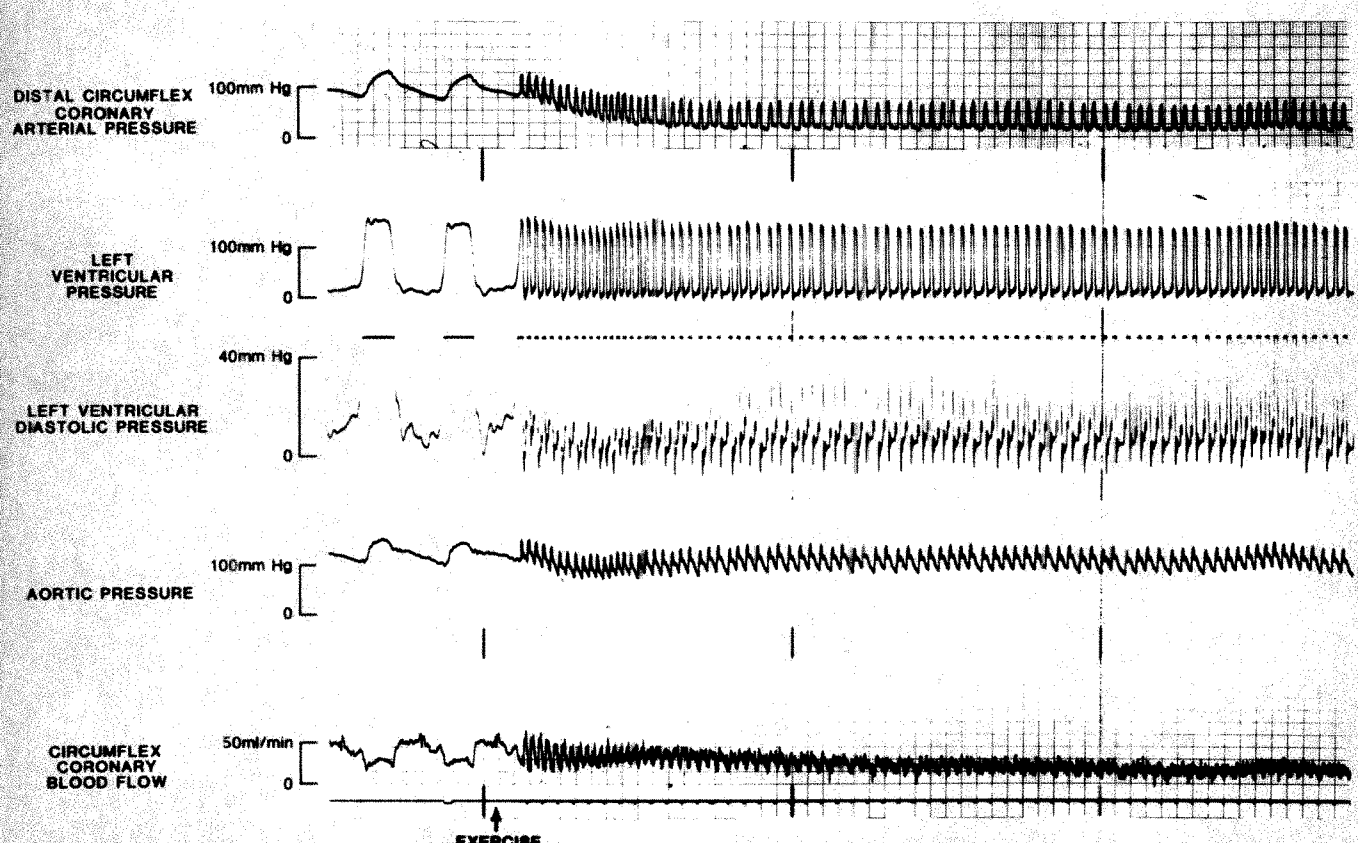

FIGURE 1. Effects of exercise in the presence of a severe circumflex coronary stenosis. Exercise resulted in a decrease in distal circumflex pressure and a decrease in flow through the stenotic circumflex artery. Each **short vertical line** at the bottom of the figure represents 1 second.

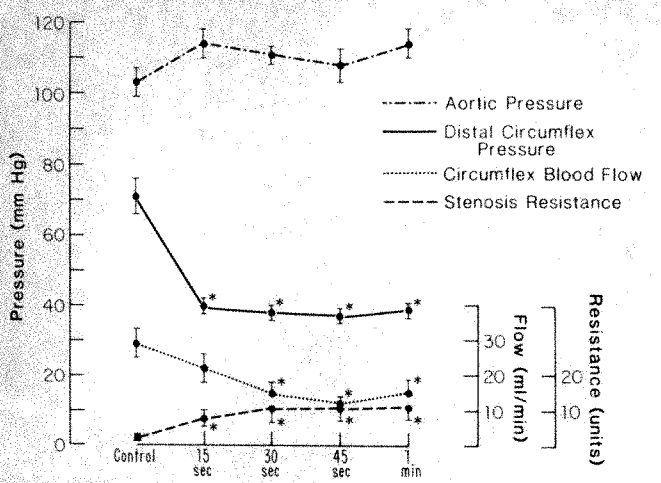

FIGURE 2. Mean hemodynamic changes during the first minute of exercise in the presence of a critical circumflex coronary stenosis. The **asterisks** indicate significant difference from control values ($p < 0.025$).

tightened further. Exercise was again performed. This was repeated until a degree of stenosis was reached at which exercise resulted in a decrease in flow through the stenotic artery.

All measurements were recorded on a Hewlett-Packard 7758B recorder at a paper speed of 1 to 50 mm/s. Mean resistance across the stenosis was expressed in resistance units (mm Hg/ml/min) and was calculated using the formula R = (P1-P2)/Q, where P1 = mean pressure in the ascending aorta, P2 = mean coronary pressure distal to the stenosis, and Q = mean circumflex coronary blood flow. All data are shown as mean values ± standard error of the mean. Significance of the differences was determined by Student's *t* test for paired data and analysis of variance.[5]

Results

In the absence of a coronary stenosis, exercise caused a consistent increase in blood flow through the circumflex coronary artery. As a stenosis was produced and made more severe, there was less of a flow increase in response to exercise. When the stenosis was very severe, in 14 experiments in 5 dogs, exercise was associated with an actual decrease in flow through the stenotic coronary artery. The decrease in coronary flow with exercise was reproducible in 4 of the 5 dogs. In each of these dogs, whenever a sufficiently severe stenosis was produced, exercise resulted in a decrease in coronary flow. In 3 of the dogs, 3 separate experiments were done in which flow decreased in the presence of a critical stenosis; in the fourth dog, 4 such experiments were done.

Figure 1 shows a tracing from 1 of the experiments in which a critical circumflex stenosis was present. Exercise resulted in a decrease in distal coronary pressure and a decrease in flow through the stenotic artery.

Figure 2 shows the mean hemodynamic changes during the first minute of exercise in those experiments in which a critical circumflex stenosis was present. Aortic pressure did not change significantly. Distal circumflex pressure fell within the first 15 seconds and did not change significantly thereafter. Stenosis resistance increased within the first 15 seconds of exercise after which it did not change significantly. Flow began to decrease during the first 15 seconds of exercise. However, this decrease did not reach statistical significance until 30 seconds after the onset of exercise. There was no further change in flow during the remainder of the first minute of exercise.

Table I shows the peak hemodynamic effects of exercise in the experiments in which a critical coronary stenosis was present. Exercise resulted in an increase in heart rate from 102 ± 7 to 151 ± 12 beats/min. There was no significant change in aortic pressure. Distal circumflex pressure fell with exercise, the pressure gradient across the stenosis increased, and stenosis resistance increased markedly. Flow through the stenotic artery fell from 29 ± 4 to 10 ± 3 ml/min. Left ventricular filling pressure increased from 9 ± 1 to 15 ± 1 mm Hg.

A decrease in flow through a stenotic artery with exercise occurred in this study only when the stenoses were sufficiently severe to result in a modest decrease in blood flow through the stenotic arteries during quiet resting conditions. Thus, in the presence of the stenoses but before exercise, flow was 78 ± 3% of the control pre-stenosis flow.

Discussion

The decrease in flow with exercise was associated with a marked increase in stenosis resistance. Calculated hydraulic resistance may vary even for a stenosis that is thought to be anatomically fixed. It has previously been shown that as flow across a stenosis increases, calculated resistance increases because the pressure gradient increases proportionally more than flow.[6,7] However, in this study the increase in resistance across the stenosis with exercise was associated with a decrease in flow, making flow changes alone an unlikely expla-

TABLE I Peak Hemodynamic Response to Exercise in the Presence of a Severe Circumflex Stenosis

	Aortic Pressure (mm Hg)	Distal Circumflex Pressure (mm Hg)	Stenosis Pressure Gradient (mm Hg)	Circumflex Blood Flow (ml/min)	Stenosis Resistance (mm Hg/ml/min)	Left Ventricular Filling Pressure (mm Hg)	Heart Rate (beats/min)
Control	103 ± 4	71 ± 5	32 ± 4	29 ± 4	2.3 ± 0.7	9 ± 1	102 ± 7

nation for the increase in stenosis resistance and suggesting that a true increase in stenosis severity occurred.

We did not attempt to calculate distal coronary arteriolar resistance in this study. Recent experiments have suggested that the resistance to flow in the distal coronary bed may be best evaluated in terms of the slope of coronary pressure-flow curves and the pressure at which flow stops.[8–10] Resistance calculations using the quotient of distal coronary pressure and flow may not be accurate. Since we did not attempt to evaluate pressure-flow curves, we could not accurately evaluate distal coronary resistance. However, the marked fall in distal coronary pressure during exercise suggests that the distal coronary arteriolar bed did dilate. This finding, in combination with the marked increase in stenosis resistance during exercise, suggests that the decrease in flow during exercise was due to an increase in the severity of the stenosis.

There are 3 possible mechanisms for the increased severity of the stenosis during exercise. The first is active constriction of the artery in the area of the stenosis. Exercise causes increased sympathetic outflow which may cause active constriction of the stenotic segment. It has previously been shown that sympathetic stimulation can decrease the diameter of large coronary arteries.[11] Although active constriction of a section of artery which is externally compressed with a snare seems unlikely, we cannot definitely exclude this possibility as a cause of the increased stenosis resistance and decrease in flow.

The second possible explanation for the increase in stenosis resistance and fall in flow is passive narrowing of the stenotic segment. It has previously been shown that the resistance of a nonfixed coronary stenosis passively changes in response to alterations in intraluminal pressure, increasing with a fall in intraluminal pressure and decreasing with a rise in intraluminal pressure.[6,12] Stenoses produced with external snares are capable of similar passive changes in resistance.[13] In the present study, exercise resulted in a marked fall in distal coronary pressure. Pressure in the stenotic segment should be as low as or lower than pressure distal to the stenosis.[14] The fall in intraluminal pressure distal to the stenosis and thus in the stenotic segment itself may have resulted in a passive decrease in the diameter of the stenotic segment. This passive narrowing of the stenosis would then result in the observed increase in stenosis resistance and the decrease in flow through the stenotic artery. Even small changes in the diameter of a severe arterial stenosis can have marked effects on flow through the stenosis.[6]

Santamore and Walinsky[15] studied isolated perfused carotid arteries in which a stenosis was produced with an external snare. The perfusion apparatus was constructed so that peripheral resistance distal to the stenosis could be decreased. These authors found that a decrease in resistance distal to the stenosis caused a decrease in stenosis diameter, as determined by radiographic analysis, and an increase in stenosis resistance. These data support the concept that the increase in stenosis resistance and fall in flow which occur in response to dilation of the distal coronary bed are due, at least in part, to passive narrowing of the stenotic segment. In the present study, in which dilation of the distal coronary bed was induced by exercise, it seems probable that a similar mechanism was responsible for the increase in stenosis resistance and the decrease in flow—namely, a decrease in intraluminal pressure in the stenotic segment resulting in a passive decrease in stenosis diameter.

A third possible cause for the decrease in flow with exercise should be mentioned. During exercise fully developed turbulence may appear in the stenotic segment. Gould[7] has suggested that when turbulence develops fully, the loss of potential energy may be so great that aortic pressure would be inadequate to maintain flow, which could then decrease without a change in stenosis diameter. Since we did not directly demonstrate a change in stenosis diameter during exercise in this study, we cannot exclude the possibility that the development of turbulence may have contributed to our findings.

The decrease in flow through the stenotic artery with exercise was associated with a modest rise in left ventricular filling pressure, suggesting that ischemia may have occurred and may have been causing regional left ventricular dysfunction. We did not attempt to continue our hemodynamic observations after cessation of exercise because of concern that the low flow through the coronary artery, which was associated with an increase in left ventricular filling pressure, might result in the animal's death. Instead, the coronary stenosis was released immediately after exercise.

The decrease in flow through the stenotic artery occurred in response to a relatively low level of exercise. We initially planned to have the animals exercise maximally on a treadmill, but this became unnecessary when we found that flow through a severely stenotic artery decreased in response to a relatively mild degree of exercise.

An increase in severity of coronary stenoses during exercise has been demonstrated clinically and has been attributed to exercise-induced coronary spasm.[16–18] It is always difficult to extrapolate from the results of animal experiments to the clinical situation. However, in the present study, when the stenosis was critically severe, exercise reproducibly resulted in a fall in flow through the stenotic artery. Although we cannot definitely exclude the possibility that the spasm played a role in our findings, it seems unlikely that spasm would reproducibly occur in response to exercise in the presence of severe stenoses and not occur in the presence of mild or moderate stenoses.

In summary, this study has shown that exercise may cause an increase in the resistance of severe nonfixed coronary stenoses and a decrease in flow through the stenotic artery. These findings suggest that in the presence of a severe, nonfixed coronary stenosis, exercise-induced myocardial ischemia may be caused by a combination of increased myocardial oxygen demand and decreased supply.

Ventricular Fibrillation Resulting From Ischemia at a Site Remote From Previous Myocardial Infarction

A Conscious Canine Model of Sudden Coronary Death

EUGENE PATTERSON, PhD, KURT HOLLAND, MD, BRIAN T. ELLER, BS, and BENEDICT R. LUCCHESI, MD, PhD

In anesthetized dogs, a 30 gauge silver wire was inserted into the lumen of the left circumflex (LC) coronary artery and myocardial ischemic injury was produced by subsequent occlusion of the left anterior descending (LAD) coronary artery for 90 minutes followed by reperfusion through a critical stenosis. Four days after acute myocardial infarction, with the dog ambulatory, the intimal surface of the LC coronary artery was injured by applying a 150 μA anodal current. Coronary artery thrombosis and subsequent reduction in coronary artery blood flow were accompanied by S-T segment changes at 132 ± 65 minutes (mean ± standard deviation [SD]) with ventricular fibrillation (VF) occurring in 29 of 30 dogs (97%) at 141 ± 60 minutes. Infarct mass in the LAD distribution was 15 ± 8% of total left ventricular mass with no histochemical evidence of irreversible ischemic injury in the LC coronary artery distribution. VF was preceded by the development of delayed electrical activity within the LC coronary artery distribution, and the development of ventricular arrhythmias accompanied by continuous local electrical activity within the subepicardial region of the distribution of the LC coronary artery. In 10 dogs with placement of a critical stenosis around the LAD coronary artery without earlier occlusion and reperfusion, LC intimal injury and subsequent thrombus formation resulted in only 2 deaths (20%) from VF. Thus, acute myocardial ischemia at a site distant to a previous myocardial infarction enhances the likelihood of primary VF in the conscious dog. This model of sudden coronary death may simulate the clinical state in man and might serve as an appropriate model for the study of electrophysiologic mechanisms associated with the development of VF and for the evaluation of potential antifibrillatory drugs.

Recent studies by Schuster and Bulkley[1] demonstrated that acute occlusion of 1 coronary artery could lead to ischemia in the myocardium supplied by a second coronary artery, if the second vessel was critically narrowed and dependent on collateral blood flow from the first coronary artery. These investigators referred to this phenomenon as "ischemia at a distant site," which could contribute to postinfarction angina pectoris and sudden coronary death, an event almost always due to unexpected ventricular tachyarrhythmias.[2,3] The high rate of recurrence of ventricular fibrillation (VF) and sudden coronary death in patients rescued from a previous event is well documented[2,4,5] and suggests that the superimposition of an ischemic episode on an already jeopardized myocardium could lead to an arrhythmia terminating in VF.

There is an urgent need for the development of pharmacologic interventions capable of preventing VF and sudden coronary death in patients identified as being at high risk. One major deficiency in this field of investigation is the lack of a suitable animal model that would permit preclinical studies to identify potentially useful therapeutic agents. Our results support the hypothesis that ischemia at a distant site (circumflex region) in a previously injured myocardium may serve as an important mechanism for the development of ventricular arrhythmias which terminate in sudden and unexpected VF. The experimental model described in this investigation is subject to ventricular tachyarrhythmias in response to programmed electrical stimulation and develops VF in the presence of regional ischemia. Therefore, the model affords the opportunity to initiate meaningful studies aimed at identifying antifibrillatory agents intended to prevent sudden coronary death in man.

Methods

Surgical Preparation of Dogs With Ischemic Myocardial Injury

Male mongrel dogs (14.6 to 25.6 kg) were anesthetized with pentobarbital sodium (30 mg/kg intravenously) and placed

on positive-pressure respiration using a volume-cycled Harvard pump. Aseptic surgical technique was employed for the insertion of cannulas in the jugular vein and carotid artery, both of which were exteriorized at the back of the neck.

The heart was exposed through a left thoracotomy in the fourth intercostal space. Both the left anterior descending (LAD) and the left circumflex (LC) coronary arteries were freed from the underlying myocardium at a distance of 0.5 to 1.0 cm from their origin. A 30 gauge Teflon®-coated silver wire, with 3 mm of the tip of a 25 gauge hypodermic needle secured on the wire's lead end to aid in penetration of the artery wall, was inserted through the wall of the LC coronary artery so that approximately 2 to 3 mm of the bare wire-needle tip assembly was within the vessel lumen and in contact with the intimal lining. The wire was secured to the epicardium with 2 sutures. The distal end of the silver wire was exteriorized at the back of the neck and would subsequently serve to deliver an anodal current of 150 μA to produce an electrolytic lesion on the intimal surface of the LC coronary artery. A Grass disk electrode was sutured to the subcutaneous tissue and completed the electrical circuit which consisted of a 9 V battery and a 250,000 Ω potentiometer placed in a series so as to allow control of the current output at the anode. The procedure was detailed by us in an earlier report.[6] In 6 of the animals, a calibrated electromagnetic flow probe was placed on the circumflex coronary artery proximal to the point of insertion of the silver wire electrode. The needle-wire assembly was inserted parallel to the inner surface of the LC coronary artery and in the absence of direct flow of current did not result in altered coronary artery blood flow, thrombus formation, or irreversible myocardial ischemic injury in the region of the distribution of the LC coronary vessel, even when left in place for 30 days.[6]

Ischemic myocardial injury was produced in the distribution of the LAD coronary artery as previously described.[7] This procedure involves the placement of a critical stenosis on the LAD coronary artery by adjusting a ligature tied around the artery and an 18 or 19 gauge needle. The needle is withdrawn and a determination made of the reactive hyperemic response to a 10 second occlusion of the LAD vessel. The constricting ligature is adjusted to reduce the reactive hyperemic response by at least 60%, but without reducing resting LAD coronary artery blood flow as recorded by an electromagnetic flow probe placed proximal to the point of vessel constriction. Once partial constriction is established, a Silastic® ligature (Retract-O-Tape®) is placed distal to the point of constriction and the LAD coronary artery is occluded for 90 minutes followed by reperfusion in the presence of the critical stenosis. The importance of the critical stenosis has been described previously by us[7] as well as by Sheehan and Epstein[8]: it reduces the incidence of VF and the development of hemorrhagic infarct on subsequent reperfusion of the myocardium in the distribution of the LAD coronary artery.

A bipolar plunge electrode consisting of a 25 gauge insulated stainless steel wire, 4 mm in length and separated by 2 mm, was placed in the ventricular septum adjacent to the right ventricular outflow tract. The electrodes were situated 1 cm from the medial border of the cyanotic area which appeared on occlusion of the LAD coronary artery. Silver disk electrodes were implanted subcutaneously for recording the electrocardiogram (lead II). The surgical incisions were closed, and the animals were given 6 mg/kg of ampicillin intramuscularly and permitted to recover from anesthesia. Figure 1 is a schematic representation of the surgical preparation of the canine heart in which the area supplied by the LAD coronary artery was subjected to ischemic injury by temporary coronary artery occlusion and reperfusion in the presence of a critical stenosis. In addition, a silver wire electrode was inserted in the LC coronary artery and will be used subsequently to induce an electrolytic lesion on the inner surface of the vessel. The bipolar electrode is to be used for programmed electrical stimulation of the heart and the induction of ventricular arrhythmias.

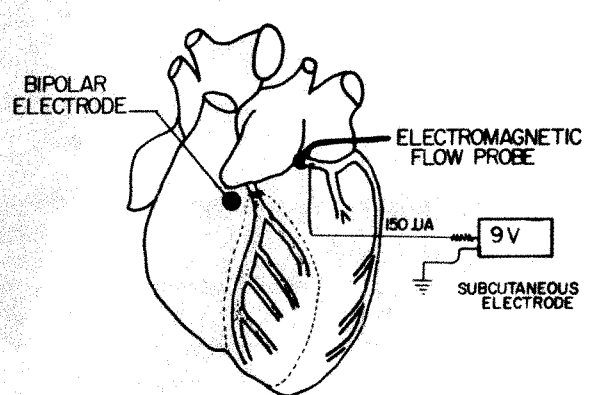

FIGURE 1. Schematic representation of canine heart in which a silver wire electrode is inserted into the LC coronary artery and is attached to the positive pole of a 9 V nickel-cadmium battery and a variable resistor which permits the current flow to be adjusted to 150 μA. The negative electrode is attached to the subcutaneous tissue. An electromagnetic flow probe is placed proximal to the intracoronary electrode. The LAD coronary artery has a critical stenosis in its proximal region, is occluded for 90 minutes, and then is reperfused in the presence of the critical stenosis which remains in place until completion of the study. A bipolar electrode in the interventricular septum is used to carry out programmed electrical stimulation after recovery from the operation. Control operated dogs were prepared in a similar manner but did not undergo occlusion of the LAD coronary artery (noninfarct group).

Experimental Procedures

Programmed electrical stimulation: The animals were returned to the laboratory after fully recovering from the operation and studied while conscious, unsedated, and resting comfortably in a sling. One, 2, and 3 ventricular premature stimuli (4 ms duration square-wave pulses, twice diastolic threshold) were applied to the interventricular septum at sequentially decreasing 10 ms intervals for S_2, S_3, and S_4 stimuli delivered from a Grass S-88 stimulator and SIU-5 stimulus isolation unit as described previously.[9,10] The ventricular stimuli from the stimulator were triggered from the R wave of the lead II electrocardiogram.

The procedure for programmed electrical stimulation can be summarized as follows: (1) Single premature ventricular stimuli (S_2) at twice diastolic threshold are introduced during normal sinus rhythm at decreasing 10 ms intervals from 350 ms until ventricular refractoriness occurs. (2) Double premature ventricular stimuli at twice diastolic threshold (S_2,S_3) are introduced during normal sinus rhythm at decreasing 10 ms intervals for S_2 stimuli from 350 ms until ventricular refractoriness occurs with S_2 to S_3 intervals of 200, 180, 170, 160, 150, 145, 135, and 130 ms. (3) Triple premature ventricular stimuli at twice diastolic threshold (S_2,S_3,S_4) are introduced during normal sinus rhythm at decreasing 10 ms intervals for S_2 stimuli from 350 ms until ventricular refractoriness occurs with S_2 to S_3 and S_3 to S_4 intervals as just stated. (4) Programmed electrical stimulation as just listed is performed during atrial pacing at rates up to 210 beats/min. (5) Intermittent ventricular pacing at rates up to 360 beats/min is performed.

The stimulation protocol was continued until reproducible sustained ventricular tachycardia could be obtained a mini-

mum of 3 times in each dog. No attempt was made to go beyond this end-point to circumvent the possible initiation of VF.

Initiation of LC coronary artery intimal injury and coronary artery thrombosis: On completion of the programmed electrical stimulation studies, the animals were placed in a quiet laboratory environment and monitored for aberrant electrocardiographic rhythms. The lead II electrocardiogram was transmitted through telemetry and stored on FM magnetic tape for subsequent analysis. Thus, the animals were studied while conscious, ambulatory, and in normal sinus rhythm. The telemetry transmitter and the 9 V battery source and variable resistor were carried in the pocket of a nylon vest (Alice King Chatham). In 6 animals in which electromagnetic blood flow probes were placed on the LC coronary artery, the study had to be conducted while the conscious, unsedated animals were maintained in a sling, thus limiting their range of movement.

Once adequate baseline recordings were obtained, a continuous direct current anodal current of 150 μA was applied to the intimal surface of the LC coronary artery. Previous unpublished studies demonstrated that an anodal current of 150 μA would reproducibly lead to oscillatory changes in the LC coronary artery blood flow within 60 to 90 minutes and that an occlusive thrombus would form within 120 to 180 minutes after initiation of current flow. An observer continuously monitored the transmitted data to detect changes in cardiac rhythm, S-T segment shifts, and LC coronary artery blood flow.

Noninfarcted control dogs with LAD coronary artery stenosis and subsequent LC coronary thrombosis: In 10 dogs that served as controls, the LAD coronary artery was constricted so as to minimize or abolish the reactive hyperemic response to a 10 second occlusion of the vessel. Unlike the previous animals in the experimental infarct group, the controls did not undergo temporary occlusion and reperfusion of the LAD coronary artery. Thus, myocardial tissue in the distribution of the vessel was not subjected to ischemic injury. As with the experimental infarct group, however, the control noninfarcted animals were subjected to electrically induced injury to the intimal surface of the LC coronary artery with subsequent formation of an occlusive thrombus and regional myocardial ischemic injury in the distribution of the occluded LC vessel.

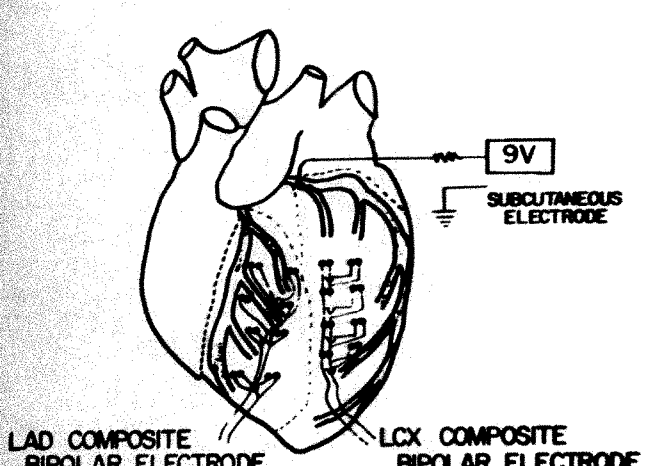

FIGURE 2. Schematic representation of the canine heart similar to that shown in Figure 1, illustrating placement of the bipolar composite electrodes used to record separate subepicardial electrograms from the region of the LAD and the left circumflex (LCX) coronary artery, so that regional electrical events in response to LC coronary artery thrombosis could be studied in the anesthetized open chest dog.

Electrophysiologic studies in the anesthetized dog: Male mongrel dogs were prepared in a manner identical to that described for the experimental group (n = 7) and for the control noninfarcted group (n = 6). The animals were returned to the laboratory 4 days after having undergone LAD coronary artery occlusion and reperfusion in the presence of a critical stenosis. The dogs were anesthetized and placed on positive-pressure respiration and the thoracotomy incision was reopened and the heart suspended in a pericardial cradle.

Sixteen pairs of insulated bipolar electrodes (0.05 mm in diameter, Teflon®-coated silver wire with 2 mm of exposed tip) were placed subepicardially in the region of distribution of both the LAD and LC coronary arteries (3 × 5 cm). Subepicardial bipolar composite recordings were obtained by summing the 16 bipolar electrode pairs so that separate recordings of composite electrograms could be obtained from each of the regions subserved by the LAD and LC coronary arteries (Fig. 2). The composite electrograms were filtered at 50 and 500 Hz. The electrograms were stored on FM magnetic tape and later recorded on a Visicorder (Honeywell model 1858) along with the lead II electrocardiogram.

Control subepicardial bipolar composite electrode recordings were obtained after which the LC coronary artery was subjected to a continuous 150 μA direct current. Measurements of the delay in the subepicardial electrograms were made on a storage oscilloscope (Tektronix model 5111). We quantitated the degree of delay and fragmentation in the subepicardial zone during the induction of thrombus formation and ischemia in the region of distribution of the LC coronary artery by measuring the maximal delay between the Q wave of the lead II electrogram and the last distinct and sharply defined activity in the subepicardial composite electrogram during normal sinus complexes. The studies were terminated 8 hours from the start of LC coronary artery simulation or on development of VF.

Quantitation of the extent of irreversible ischemic myocardial injury: At the conclusion of each experiment the heart was removed, examined, and prepared for histochemical staining to identify irreversibly damaged myocardium. The LC coronary artery was examined for thrombus adherent to the site of intimal injury or in the distal branches of the vessel. The heart was sectioned transversely, apex to base, into 5 mm thick sections which were incubated at 39°C in a 0.5% solution of triphenyltetrazolium hydrochloride in 0.01 *M* phosphate buffer at pH 7.4. The histochemical stain is reduced in the presence of dehydrogenase enzyme activity, thus rendering viable myocardial tissue an intense "brick-red" color and clearly demarcating irreversibly injured tissue which retains a pale coloration. Recent studies[11] confirm that failure of myocardial tissue to reduce triphenyltetrazolium correlates with the presence of irreversibly injured myocardium and agrees with previous observations from our laboratory.[7]

In the control animals and in the groups used for electrophysiologic studies, thioflavin-S (10 ml of a 5% solution) was injected into the left atrial appendage just before sacrifice by the electrical induction of VF. The heart was removed, sectioned, and stained as described previously. The sections were viewed under ultraviolet light to determine the pattern of distribution of the thioflavin-S which is a flow-dependent fluorescent stain. The appearance of the stain in the region of distribution of the LAD coronary artery was used to confirm the patency of the vessel in which a critical stenosis had been established 4 days earlier. After being viewed under ultraviolet light the ventricular sections were stained in triphenyltetrazolium chloride as described herein.

Statistics: Values for the data are presented as mean ±

standard deviation. Fisher's exact test was used to analyze the differences in survival between operated control animals and those with experimental infarct. A 2-way analysis of variance was used to analyze for differences in the means between the experimental and the control groups.

Results

Programmed electrical stimulation in the conscious dog with experimentally induced myocardial infarction (LAD coronary artery occlusion and reperfusion): Thirty dogs were subjected to temporary occlusion of the LAD coronary artery and reperfusion in the presence of a critical stenosis, and after full recovery from the operation, the animals were evaluated for the presence of myocardial electrical instability using programmed electrical stimulation. Single, double, and triple premature ventricular stimuli were introduced into the ventricular septum as described previously. Myocardial electrical instability as revealed by electrically inducible ventricular arrhythmias was manifest as either nonsustained ventricular tachycardia in 16 dogs (53%), sustained ventricular tachycardia in 7 dogs (23%), or VF in 4 dogs (13%). Of the 30 animals evaluated on the fourth day after myocardial infarction, 27 (90%) had electrically inducible ventricular arrhythmias in response to programmed cardiac stimulation. The results obtained with programmed electrical stimulation are summarized in Table I and a representative experiment showing the induction of a nonsustained ventricular tachycardia is presented in Figure 3 (top panel). Induced sustained ventricular tachycardia was terminated by rapid ventricular pacing. Once repeatedly initiated nonsustained ventricular tachycardia had been observed in a given animal, using 1 or more modes of atrial or ventricular stimulation, we did not attempt more aggressive stimulation using closer ventricular coupling intervals or faster rates of ventricular pacing so as to avoid excess attrition of animals because of electrically induced VF. In the 4 dogs in which VF developed during programmed electrical stimulation, resuscitation was successfully achieved by transthoracic direct current shock.

TABLE I Incidence of Myocardial Electrical Instability on Day 4 After Myocardial Infarction

	LAD Coronary Artery Infarct Group (n = 30)		Control Group (n = 10)	
	n	%	n	%
Not inducible	3	10	10	100
Nonsustained VT	16	53	...	...
Sustained VT	7	23	...	...
VF	4*	13	...	...

* Defibrillated using transthoracic direct current cardioversion (200 to 250 W-s). VT = ventricular tachycardia.

Programmed electrical stimulation in the conscious dog with an LAD coronary artery critical stenosis, but without myocardial ischemic injury (control, noninfarct group): Programmed electrical stimulation was performed in 10 conscious dogs on the fourth day after placement of a critical stenosis in the LAD coronary artery, but in which myocardial tissue was not subjected to a period of ischemia leading to irreversible injury. Neither nonsustained nor sustained ventricular tachyarrhythmia could be induced in any of the animals through the use of programmed electrical stimulation. Thus, observations in the 10 animals without previously induced ischemic myocardial injury contrast with those obtained in animals that had been subjected to LAD coronary artery occlusion and reperfusion in which myocardial electrical instability could be demonstrated 4 days later in 27 of 30 dogs undergoing provocative electrical stimulation of the heart.

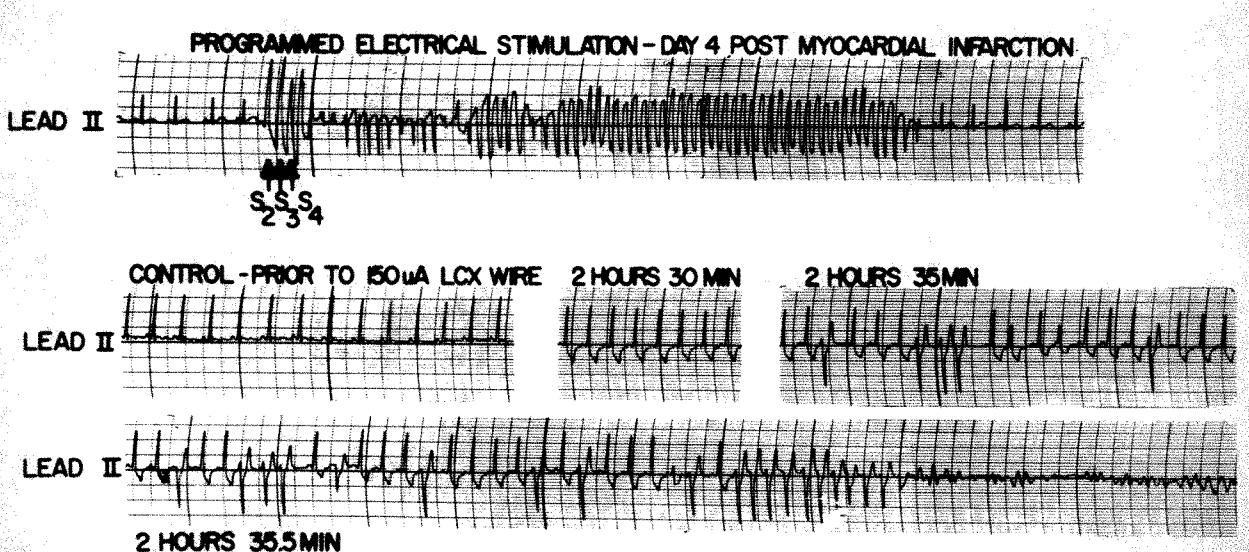

FIGURE 3. Ventricular fibrillation in the conscious dog. On day 4 after myocardial infarction, 3 premature ventricular stimuli at twice diastolic threshold are applied to the interventricular septum (coupling intervals of 180, 150, and 150 ms) **(upper panel)**. A polymorphic nonsustained ventricular tachycardia is produced. Lead II electrocardiograms before and after stimulation of the intimal surface of the left circumflex (LCX) coronary artery **(lower panels)** show the development of S-T segment depression followed by disturbances in cardiac rhythm. At 2 hours and 35.5 minutes, the ventricular rhythm degrades to VF.

TABLE II **Time Course for the Development of Electrocardiographic Changes in the Conscious Dog in Response LC Coronary Artery Thrombosis**

4 Days After MI	LAD Coronary Artery Infarct Group (n = 30)	Control Noninfarct Group (n = 10)
Minutes to S-T segment change	132 ± 65	133 ± 70
Minutes to premature ventricular contractions	136 ± 68	218 ± 192
Minutes to ventricular tachycardia	138 ± 58	280 ± 190
Minutes to VT or VF	141 ± 60	420
VF	29 (97%)	2 (20%)

No significant differences between groups. MI = myocardial infarction.

Ischemia at a distance (circumflex region) in the dog previously subjected to myocardial ischemic injury and (LAD region) reperfusion: On completion of the protocol for programmed electrical stimulation the animals in both the infarct group (n = 30) and the control noninfarct group (n = 10) were subjected to direct anodal current of 150 μA applied to the intimal surface of the LC coronary artery through the previously implanted silver wire electrode. The animals were conscious and either unrestrained or limited in mobility by being placed in a sling. As we demonstrated previously,[6,12–14] electrically induced lesions on the intimal surface of the LC coronary artery result in platelet aggregation and transient oscillation in coronary blood flow associated with changes in the S-T segment,[14] suggesting subendocardial or transmural ischemia.

Continuous monitoring of the lead II electrocardiogram in each of the 30 animals during LC coronary artery stimulation showed that the mean time to initial S-T segment changes (>0.3 mV) was 132 ± 65 minutes, with some animals showing S-T segment depression (n = 25) and others manifesting ischemia by developing S-T segment elevation (n = 5). Premature ventricular beats were observed initially at a mean time of 136 ± 68 minutes after initiation of current flow to the LC coronary artery with the development of VF at 141 ± 60 minutes in 29 of 30 animals (97%) with chronic myocardial infarction due to LAD coronary artery occlusion and reperfusion in the presence of a critical stenosis (Table II). All animals were in normal sinus rhythm before the initiation of LC coronary artery stimulation and the development of S-T segment changes in the lead II electrocardiogram. The mean heart rate was 128 ± 19 beats/min. With the development of S-T segment alterations and presumably ischemia due to changes in LC coronary artery blood flow, the sinus rate increased to 169 ± 26 beats/min ($p < 0.05$). Premature ventricular beats or ventricular tachyarrhythmias were not considered in all instances as premonitory signs of VF. In 5 animals, VF was the initial electrocardiographic disturbance associated with the development of S-T segment changes, so that the fatal rhythm developed in the absence of a warning arrhythmia. Figure 3 is taken from a series of electrocardiographic recordings from 1 dog in which nonsustained ventricular tachycardia developed in response to programmed electrical stimulation when tested 4 days after LAD coronary artery occlusion and reperfusion. Subsequent anodal current injury in the LC coronary artery resulted in progressive changes in the electrocardiogram which first showed S-T segment depression and eventually culminated in VF. The time from the first appearance of changes in the S-T segment until the onset of VF showed wide variation among the 30 animals studied. In 6 animals the elapsed time between these events was <15 seconds.

In 6 conscious animals, continuous recordings were made of the lead II electrocardiogram, arterial blood pressure, and LC coronary artery blood flow during the induction of low amperage electrical stimulation to the intimal surface of the LC vessel. The initial LC coronary artery blood flow was 40 ± 8 ml/min and the mean arterial blood pressure averaged 101 ± 9 mm Hg. LC coronary blood flow was reduced to 4 ± 6 ml/min ($p < 0.01$) and was accompanied by S-T segment changes >0.3 mV with the maximal change occurring at 114 ± 59 minutes after initiating intimal stimulation of the coronary artery. Mean arterial blood pressure was reduced to 87 ± 9 mm Hg ($p < 0.05$). VF developed in each of the 6 animals within 131 ± 60 minutes from the induction of LC coronary artery stimulation. Figure 4 is a representative tracing from 1 of the conscious animals showing the sequence of changes in blood pressure, LC coronary blood flow, and the lead II electrocardiogram during the development of an ischemic episode in the distribution of the LC coronary artery which terminated in VF. In this particular experiment, there was an abrupt cessation of LC coronary artery blood flow, S-T segment depression appeared, and within 15 minutes VF developed.

During these studies the induction of intimal injury to the LC coronary artery was associated with marked alterations in coronary artery blood flow as recorded with an electromagnetic flow probe. Figure 5 is a representative tracing in which arterial blood pressure, the lead II electrocardiogram, and phasic and mean LC coronary artery blood flow are recorded from a conscious dog before and after initiation of current flow to the vessel wall. There is a gradual decrease in amplitude of the phasic coronary blood flow tracing without a change in the mean LC coronary artery blood flow. This is followed by the spontaneous development of a marked reactive hyperemic response (second panel, 1 hour, 9 minutes). Within 10 minutes after the previous record, there is a repetition of the event in which the phasic flow responses are attenuated only to be followed by a reactive hyperemic response. These coronary blood flow changes are cyclic until at 2 hours after the initiation of anodal stimulation of the vessel, coronary flow in the circumflex decreased to 0 and remained at this level until the fibrillation occurred shortly thereafter. Marked disturbances in the electrocardiogram occurred whenever the phasic flow response was attenuated and especially during the development of the reactive hyperemic response. In some instances, VF developed during the active arrhythmic phase associated with the

FIGURE 4. Ventricular fibrillation resulting from thrombotic coronary artery occlusion. Arterial pressure tracings, a lead II electrocardiogram, and left circumflex (LCX) coronary blood flow (mean and phasic) are shown before (control) and after stimulation of the intimal surface of the LC coronary artery. At 2.5 hours, S-T segment depression is present in the lead II electrocardiogram and LC coronary artery flow is 0 ml/min. Fifteen minutes later, sustained VF is observed. An occlusive thrombus, weighing 18 mg, was removed from the LC coronary artery at autopsy.

reactive hyperemic response and could account for our inability to identify occlusive thrombi in all animals dying suddenly as a result of VF.

Electrical induction of LC coronary artery thrombosis in the conscious dog with LAD coronary artery stenosis: Ten dogs serving as controls underwent stenosis of the LAD coronary artery, but were not subjected to occlusion and reperfusion. On the fourth postoperative day, a 150 μA anodal current was applied to the intimal surface of the LC coronary artery while the animals were conscious and ambulatory. Changes in the S-T segment, either elevation or depression, occurred at 133 ± 70 minutes and this value did not differ significantly from that seen in the previous group with chronic myocardial infarction (Table II). The onset of ventricular ectopic beats and the development of ventricular tachyarrhythmia in response to ischemia in the distribution of the LC coronary artery were delayed in the control group compared with the experimental animals with previous LAD coronary artery occlusion and reperfusion. Although 97% of the animals with previous myocardial injury developed VF in response to ischemic changes due to alterations in circumflex coronary artery blood flow, only 20% of the control animals ($p < 0.004$) died suddenly as a result of acute ischemia in the distribution of the LC coronary artery. Data for both the experimental infarct group and the control, noninfarct animals are presented in Table II.

Electrophysiologic studies in the anesthetized dog with previous LAD coronary artery occlusion

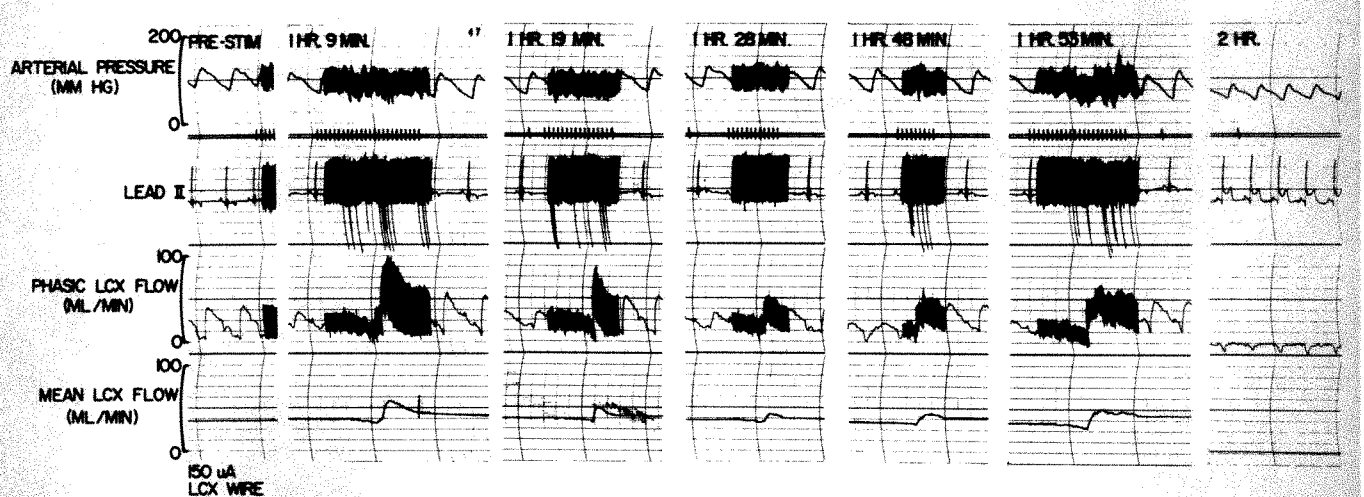

FIGURE 5. Representative recordings of arterial blood pressure, lead II electrocardiogram, and phasic and mean left circumflex (LCX) coronary artery blood flow from a conscious dog that had undergone LAD coronary artery occlusion and reperfusion in the presence of a critical stenosis. The **first panel on the left** is a control tracing. Subsequent recordings were made after the initiation of LC coronary artery stimulation with a 150 μA direct anodal current. See text for description.

and reperfusion and in control animals without chronic myocardial infarction: The need to obtain electrocardiographic recordings from the subepicardial region of the heart made it necessary to study animals in the anesthetized state and with the heart exposed. Seven dogs with chronic myocardial infarction due to previous LAD occlusion and reperfusion in the presence of a critical stenosis and 6 control dogs with LAD coronary artery stenosis but without chronic myocardial infarction comprised the study groups. Both groups were subjected to intravascular injury in the circumflex coronary artery by application of a 150 μA current while subepicardial bipolar composite electrograms were recorded from the respective areas of distribution of the LAD and LC coronary arteries. Recordings of the lead II electrocardiogram and the 2 sets of subepicardial bipolar electrograms were stored on FM magnetic tape and played back on a Honeywell Visicorder. After the control data were obtained, a 150 μA anodal current was applied to the LC coronary artery.

Figure 6 is a representative experiment showing the lead II electrocardiogram and separate subepicardial composite electrode recordings from the regions of distribution of the LAD and LC coronary arteries. Composite bipolar electrograms from the LAD and LC coronary artery distributions show discrete deflections without evidence of conduction delay or fragmentation of the normally conducted beats (upper left panel). Despite a region of chronic myocardial injury in the distribution of the LAD artery, there is no evidence of continuous electrical activity during electrical diastole from the subepicardial bipolar composite electrode overlying the area of chronic injury. With the appearance of S-T segment elevation in the lead II electrocardiogram (upper right panel), there is a progressive increase in conduction delay and fragmentation and a decrease in voltage amplitude and appearance of continuous diastolic electrical activity in the composite electrogram recording from the LC coronary artery distribution, whereas the composite bipolar recordings from the region supplied by the LAD coronary artery continue to show a uniform pattern of activation and become disorganized only when there is further disorganization of ventricular electrical activity in the limb lead electrocardiogram. The results in each of the animals with previous LAD coronary artery occlusion and reperfusion and subsequent acute ischemia in the region of the LC coronary artery were similar to those discussed herein (Table III). It was obvious that subepicardial delay of normally conducted beats and persistent diastolic activation developed initially in the region of myocardium supplied by the LC coronary artery and

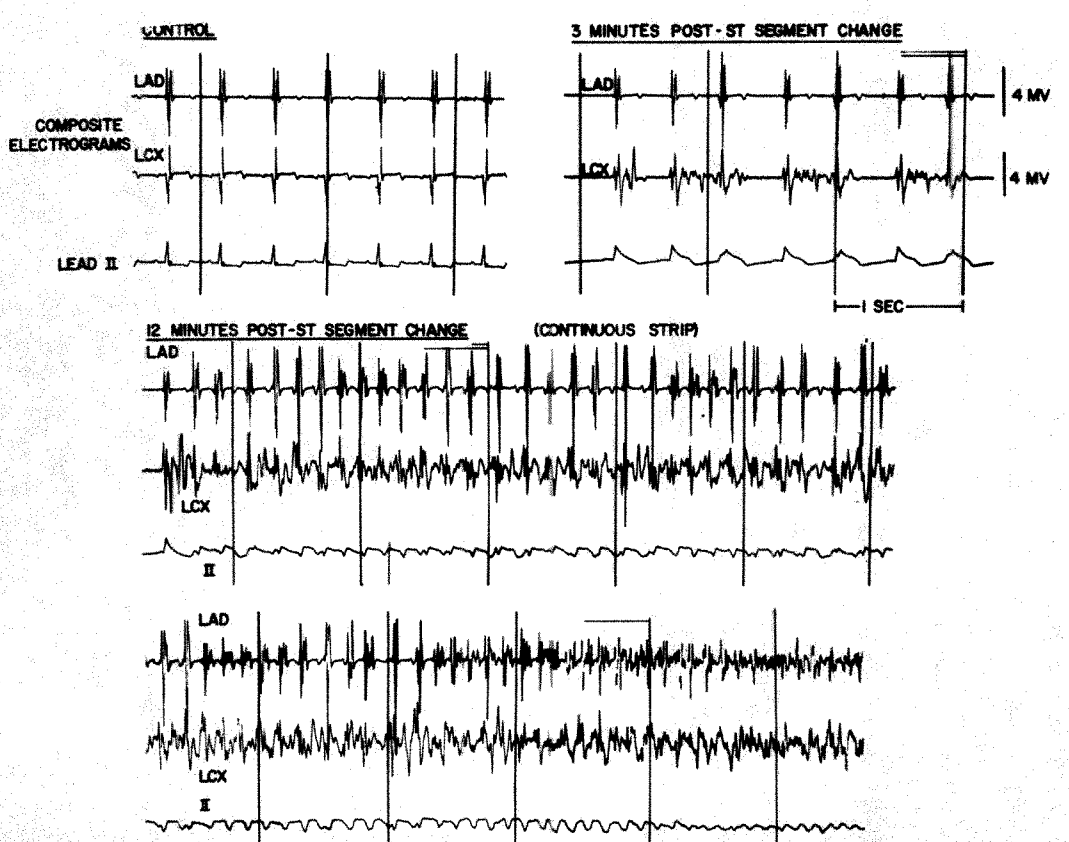

FIGURE 6. Canine model of sudden coronary death.[2] Control electrograms from the LAD and left circumflex (LCX) distributions are shown in conjunction with a lead II electrocardiogram. Three minutes after S-T segment elevation, delayed and fractionated electrical activity appeared in the circumflex distribution, spanning diastole and producing premature ventricular beats. Twelve minutes after development of S-T segment elevation, a sustained ventricular tachycardia leading to VF was present. Continuous electrical activation within the LC distribution was present from the initiation of tachycardia to VF.

TABLE III **Electrocardiographic Changes in the Anesthetized Canine During Induction of LC Coronary Artery Thrombosis**

4 Days After MI	LAD Coronary Infarct Group (n = 7)	Control Noninfarct Group (n = 10)
Minutes to S-T segment change	98 ± 58	122 ± 38
Minutes to premature ventricular beats	108 ± 55	128 ± 62
Minutes to VT	109 ± 54	196 ± 80
Minutes to VF	113 ± 55	126 (n = 1)

No significant differences between day 4 postinfarct group and control group. MI = myocardial infarction; VT = ventricular tachycardia.

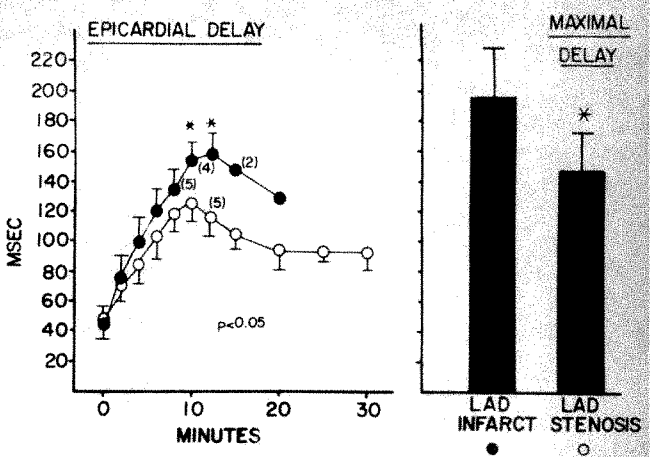

FIGURE 7. Epicardial delays (mean ± standard deviation) as recorded from the myocardial region supplied by the LC coronary artery in dogs that underwent occlusion and reperfusion of the LAD coronary artery (LAD infarct, n = 7) and in a group of dogs without ischemic injury but with a critical stenosis on the LAD coronary artery (LAD stenosis, n = 6). Myocardial activation time in each group before the development of myocardial ischemia was <60 ms. The presence of S-T segment changes was accompanied by the development of delayed electrical activation within the LC coronary artery distribution. Delay at 10 and 12 minutes after S-T segment changes was significantly greater in the LAD infarct group. The maximally observed delay for any normal sinus beat in the first 20 minutes after the onset of S-T segment changes was significantly greater in the LAD infarct group.

was progressive, so that the frequency and severity of the ventricular arrhythmia increased as did the delay in activation in the ischemic heart. Figure 7 shows the changes in epicardial delay as recorded in the experimental infarct animals with previous LAD coronary artery occlusion and reperfusion as compared with dogs with only LAD coronary artery stenosis. The peak epicardial delay in the 2 groups was observed within 10 to 12 minutes after the appearance of S-T segment changes in the lead II electrocardiograms and was significantly greater in the group with previous myocardial ischemic injury as compared with the noninfarcted control animals ($p < 0.05$). Subepicardial composite bipolar electrocardiograms of the region of distribution of the LAD coronary artery in both groups of animals were not altered initially by the subsequent development of ischemia in the myocardial region supplied by the LC coronary artery. In the 7 experimental animals with previous ischemic myocardial injury, VF developed in all after the development of ischemic S-T segment changes in the limb lead electrocardiogram and the appearance of conduction delay and fragmentation in the subepicardial composite bipolar electrograms of the region supplied by the LC coronary artery. However, in only 1 of 6 dogs with LAD coronary artery stenosis and without previous ischemic injury did VF develop in response to ischemia in the myocardial region supplied by the LC coronary artery. Maximal subepicardial delay of normally conducted beats was most pronounced in the group with previous ischemic injury in the region of the LAD coronary artery, and this group displayed a uniform potential to develop VF within 20 minutes after the onset of S-T segment changes (Fig. 7). The development and magnitude of changes in the subepicardial conduction delay appear to be related temporarily to the spontaneous occurrence of ventricular arrhythmias and VF.

Coronary artery thrombosis and irreversible myocardial ischemic injury: VF and sudden death occurred more frequently in those animals subjected to previous LAD coronary artery occlusion and reperfusion. Postmortem examination of the LC coronary artery distal to the point of electrode insertion revealed a thrombus that averaged 11 ± 7 mg. In 5 animals, no evidence of LC coronary artery thrombosis could be found at the site of intimal injury. In 12 animals the thrombus averaged less than 5 mg. Complete occlusion of the lumen of the LC artery by the thrombus was not observed in 18 of 30 animals dying suddenly. Because of instantaneous death in this group and because ischemia in the distribution of the LC existed only briefly before the onset of VF, postmortem staining of the ventricular sections with triphenyltetrazolium chloride did not reveal any evidence of irreversible ischemic injury in the LC distribution. However, because animals in the infarct group had been subjected to previous occlusion and reperfusion of the LAD coronary artery, triphenyltetrazolium staining showed an anterior wall infarct that averaged 15 ± 8% of total left ventricular mass.

In the noninfarcted control dogs subjected to LAD coronary artery stenosis, subsequent induction of intimal injury of the LC coronary artery produced a mean thrombus of 48 ± 40 mg (range 4 to 135 mg) and in 9 of 10 animals resulted in total occlusion of the vessel. The thrombus was significantly larger ($p < 0.05$) in the control group, probably because 8 of 10 animals survived 24 hours, allowing time for continued development and organization of an obstructive lesion. In only 2 of the 10 animals in this group did VF develop (Table II). Postmortem examination in the remaining 8 dogs 24 hours later showed an infarct mass in the distribution of the circumflex coronary artery which averaged 18 ± 12% of the total left ventricle. In the control group there was no evidence of myocardial tissue injury in the region of distribution of the stenosed LAD coronary artery. Furthermore, the administration of thioflavin-S just before sacrifice of the animals resulted in perfusion of the anterior wall segment supplied by the stenosed

vessel. Thus, despite total thrombotic occlusion of the LC coronary artery, in the presence of a critical stenosis in the LAD coronary vessel, VF or sudden death occurred in only 20% of the animals as compared with 97% of the animals that had chronic myocardial infarction due to previous ischemic injury resulting from occlusion and reperfusion of the LAD coronary vessel. In the latter group, fatal VF occurred despite the fact that the LC coronary artery did not always undergo total occlusion. Thus, a brief ischemic episode due to alterations in coronary artery blood flow in a region remote from a previous myocardial infarction is capable of leading to a rhythm disturbance that has the potential to initiate VF and sudden coronary death.

Discussion

Coronary artery disease is responsible for over 90% of sudden deaths occurring each year in the general population. In a study by Lie and Titus,[15] 62 to 74% of the hearts of victims of sudden and unexpected death showed evidence of acute or old myocardial infarction. Coronary artery stenosis was present in the heart in over 90% of these victims, and specialized staining methods provided evidence of acute myocardial ischemia in up to 81% of the hearts examined. McQuay et al[16] suggested that postinfarction angina might occur and contribute to death in as many as 20% of patients with fatal infarcts. The recent and elegant studies by Schuster and Bulkley[1] add further support to the concept that ischemia at a site remote from a previous myocardial infarction could contribute to sudden coronary death.

The animal model described in this report demonstrates that an acute ischemic event, when superimposed on a ventricular myocardium with a history of previous ischemic injury, can lead to an electrophysiologic disturbance culminating in VF. However, myocardial ischemia in the distribution of the LC coronary artery in the absence of a previous myocardial infarction carried a low risk of lethal arrhythmia, suggesting that disorganization of cardiac rhythm is more likely to occur in a ventricle that serves as a proper substrate for initiating and maintaining a rhythm capable of degenerating into VF. Through the use of programmed electrical stimulation, we as well as others have demonstrated that occlusion and reperfusion of the LAD coronary artery renders the canine heart susceptible in the long term to electrical induction of nonsustained or sustained ventricular tachycardia, or both.[9,10,17] Histologic examination of the myocardium subjected to occlusion and reperfusion showed viable myocardium within the necrotic region, suggesting that salvaged myocardial fibers may provide reentrant pathways causing sustained tachyarrhythmias.[17–20] Previous experimental and clinical studies have provided sufficient evidence that ventricular tachyarrhythmias in response to programmed electrical stimulation are due to reentry and less likely to be related to triggered automaticity or to other electrophysiologic mechanisms.[21–26] Data in the present study agree with previously published observations on the reentrant nature of induced arrhythmias. The existence of conduction defects in the epicardium of the infarcted canine heart after experimentally induced myocardial infarction has been described[24,27] and shown to be associated with reentrant ventricular arrhythmias which can be induced using the same techniques of programmed electrical stimulation practiced in the clinical laboratory. Thus, the animal model in which myocardial ischemic injury has resulted from occlusion and reperfusion of the LAD coronary artery renders the heart highly susceptible to sustained ventricular tachyarrhythmias which can be terminated by single or multiple electrical stimuli.

From our observations we assume that electrically induced arrhythmia arises from myocardium within or adjacent to the infarct and depends on the heterogeneous nature of the damaged tissue due to reperfusion after a period of ischemia.[17–20] This assumption is supported by our ability to regularly record the presence of continuous electrical activity originating from the ischemic zone (LC region) and bridging the diastolic interval between the initiating and reentrant beats as well as between consecutive reentrant beats. However, this disturbance alone does not explain why the chronically damaged heart is, for a variable period of time, susceptible to the development of VF. Neither we nor others[17–20] have noted any great tendency for VF to develop in the chronically damaged heart during programmed electrical stimulation in which the provocative stimuli were limited to variables that produced sustained or nonsustained ventricular tachycardia, or both. The addition of a second, albeit remote, ischemic episode due to initiation of an occlusive thrombotic event in the LC coronary artery causes an additional region of the heart to support a reentry pattern which ultimately engages the chronically injured region, thus leading to VF. It appears as if a critical mass of myocardium capable of providing a region of sufficient length to support a reentrant pathway is essential for the development and maintenance of spontaneous VF. Furthermore, regional myocardial ischemia as well as decreased collateral blood flow to the area of chronic myocardial infarction would result from a disturbance in LC coronary artery blood flow. Myocardial ischemia would decrease the threshold for the development of VF, thereby enhancing the possibility of fatal arrhythmia. In addition, tachyarrhythmia resulting from ischemia in the region of the LC coronary artery would further enhance the tendency for VF to develop.[28]

Our evidence illustrates that electrically induced injury to the LC causes regional disturbances in coronary blood flow, resulting in ectopic ventricular activity associated with continuous electrical activity as recorded with subepicardial bipolar composite electrodes in the acutely ischemic LC region. The bridging of the diastolic interval was associated with ventricular tachycardia due most likely to a reentrant mechanism as discussed herein and supported by the elegant observations of El-Sherif et al.[24,29] Subsequent to this event and just before the onset of VF, continuous diastolic electrical activity developed within the region of the LAD coronary artery. One might assume that overlapping of the 2 regions of reentry would result in

a relatively large zone of diastolic electrical activation capable of sustaining the reentrant mechanism leading to VF. This concept that a sufficient reentrant zone is required for the development of VF is supported by our observation that thrombotic occlusion of the LC coronary artery in the presence of LAD coronary artery stenosis, but without a previous myocardial infarction, seldom resulted in VF. This might be explained on the basis of a lack of a critical mass of myocardium with altered electrophysiologic properties capable of initiating and sustaining VF. Thus, the addition of a remote site of ischemia in the presence of chronic myocardial infarction may be a major factor leading to the development of VF.

We are well aware that not all authorities would agree with the interpretation of our results and the analysis of the subepicardial electrograms. We suggest that although continuous electrical activity is expected within an area of reentry, continuous activity is not, in itself, proof of reentry.[30,31] In contrast to many previous studies, we employed a composite electrode made up of an array of subepicardial recording sites. Furthermore, the electrical event being recorded is that which precedes the development of VF and is in response to an acute ischemic episode which in the majority of instances was transmural myocardial ischemia due to interruption in LC coronary artery blood flow. Using a subepicardial bipolar composite electrode recording arrangement similar to that described herein, Kaplinsky et al[32] analyzed the exact time course of ventricular arrhythmias after coronary artery ligation and correlated these events with the local disturbance of activation in the ischemic zone. Their data show that VF of immediate (first 10 minutes) ventricular arrhythmias is associated with severe subepicardial delay of the normally conducted beats, whereas VF of the delayed (12 to 30 minutes) arrhythmias was not associated with subepicardial delay. The development of VF in the model described herein is closely related to that of the immediate variety discussed by Kaplinsky et al.[32]

It is difficult to extrapolate from the animal experiment to the clinical situation. However, the animal model of "sudden coronary death" presented in this study may provide a useful tool to explore in greater detail those electrophysiologic events associated with the development of VF in a totally physiologic setting not requiring anesthesia and not being dependent on the application of external electrical stimui to initiate and sustain the development of VF. Furthermore, we view this animal model as a potentially useful adjunct in the final preclinical evaluation of pharmacologic interventions designed to prevent VF.[33]

Quantitative Assessment of Infarct Size Reduction by Coronary Venous Retroperfusion in Baboons

GRAYSON G. GEARY, MB, FRACP, GREGORY T. SMITH, PhD, GLEN T. SUEHIRO, CHARLES ZEMAN, BENJAMIN SIU, and J. JUDSON McNAMARA, MD

Initial favorable reports in which coronary venous retroperfusion was begun after acute coronary artery occlusion have demonstrated a reversal of ischemic injury and improved left ventricular function. However, little information has been generated to document the extent to which retroperfusion may decrease ultimate histologically determined infarct size. The objective of the present study was to evaluate the effectiveness of retroperfusion in reducing infarct size by using an accurate quantitative method in which infarct size was related to the size of the anatomic perfusion bed of the occluded artery (region at risk for infarction). In an experimental group of 5 baboons, the left anterior descending coronary artery was occluded and coronary venous retroperfusion started 1 hour after occlusion. After a 4-hour period of occlusion, retroperfusion was discontinued and anterograde perfusion was simultaneously restored. A control group of 5 baboons underwent an identical procedure without retroperfusion. Twenty-four hours after occlusion, hearts were excised and the previously occluded left anterior descending coronary artery as well as the adjacent arteries were injected with microvascular dye to delineate the perfusion bed of the occluded artery. Planimetry of serial cross-sections of the left ventricle enabled the size of the perfusion bed of the occluded artery and size of the infarct to be determined. The mean percentage of the perfusion bed infarcted in the control group was 94.1 ± 0.9 (mean ± standard error) and in the retroperfused group was 57.4 ± 3.5 ($p < 0.001$). Hence, the results demonstrated that when retroperfusion was initiated after 1 hour of coronary occlusion, the mean percentage of the perfusion bed salvaged was increased by 36.7%.

Several investigators have shown that selective synchronized coronary venous retroperfusion, when started after acute coronary artery occlusion, may result in partial reversal of ischemic injury[1–3] and improved left ventricular function.[1,2,4] Despite these favorable reports, little information has been available as to whether retroperfusion reduces infarct size as histologically assessed. In our previous study in the baboon, we demonstrated that retroperfusion begun 15 minutes after coronary artery occlusion combined with later anterograde reperfusion substantially reduced the percentage of the left ventricle ultimately infarcted.[5] Because retroperfusion was initiated early at a time when the entire ischemic region has been shown to remain viable,[6] the optimal effectiveness of the retroperfusion system was demonstrated.

The results of the initial study demonstrated the capability of the retroperfusion system to maintain the viability of ischemic myocardium. Because of these results, the next step was to examine the effectiveness when it was delayed for a period consistent with its clinical use. Therefore, the objective of the present study was to examine the effectiveness of coronary venous retroperfusion in reducing infarct size when retroperfusion was delayed for 1 hour after coronary occlusion. Additionally, a more accurate methodologic approach was employed to determine the degree of myocardial salvage achieved by retroperfusion. Infarct size was related to the size of the anatomic perfusion bed of the occluded artery (region at risk for infarction). This technique eliminated the variability in infarct size which may occur due to inherent variability in the size of the anatomic perfusion bed of an occluded artery. Thus, a

more accurate quantitative assessment of myocardial salvage by retroperfusion may be determined.

Methods

Surgical preparation: Ten baboons (Papio anubis), 20 to 26 kg, were initially sedated with ketamine hydrochloride (10 mg/kg intramuscularly). Anesthesia was induced and maintained with intravenous infusions of sodium thiopental (2 mg/kg). A standard lead II electrocardiogram was monitored. Baboons were intubated with a cuffed endotracheal tube and ventilated with a Harvard volume respirator maintaining an arterial pH of 7.40 ± 0.05. Supplemental oxygen was administered as necessary to maintain an arterial oxygen saturation of at least 95%. Arterial pressure was monitored by an 8Fr stiff-walled catheter advanced through the left femoral artery. Intravenous fluids were administered via a catheter through the left femoral vein. A 9Fr cannula was inserted into the right femoral artery and served as the source of arterialized blood for the coronary venous retroperfusion system. A mid-sternal thoracotomy was performed and the heart suspended in a pericardial cradle. The left anterior descending coronary artery was dissected free from the anterior interventricular vein distal to the first diagonal branch. A 3-0 Mersilene® snare was placed around the dissected left anterior descending coronary artery for subsequent ligation. An electromagnetic flow catheter (Millar Instruments, Houston, Texas) was inserted into the pulmonary artery by means of a purse-string suture for measurement of cardiac output. Left ventricular pressure, the rate of rise of left ventricular pressure, and left ventricular end-diastolic pressure were monitored with use of a micromanometer tip catheter (Millar) which was inserted through a 12-gauge cannula into the left ventricle. A 6Fr thin-walled preshaped polyethylene retroperfusion catheter was inserted into the right atrium through a purse-string suture in the atrial appendage. The catheter was then advanced through the coronary sinus to position its tip at the junction of the great cardiac vein and the anterior interventricular vein. A slow infusion of heparinized saline solution was maintained through the catheter to ensure patency until retroperfusion was initiated. Two rows of 6 unipolar atraumatic epicardial electrodes spaced at 5 mm intervals were placed across the anticipated region of ischemia parallel to the minor axis of the left ventricle. Recordings from the electrode rows were used to assess directional changes in S-T segment elevation during periods of occlusion, retroperfusion, and anterograde reperfusion.

Coronary venous retroperfusion system: The coronary venous retroperfusion system is schematically illustrated in Figure 1. It is similar to our previously described system[5] except that a commercially available pulsatile pump and pumping chamber were employed. The right femoral artery served as the source of arterial blood which flowed through an occlusive roller pump calibrated to accurately deliver the small required blood flow rates. The roller pump provided a continuous blood flow of 40 to 50 ml/min into a bladder contained within a pediatric pulsatile bypass chamber (Kontron Cardiovascular, Everett, Massachusetts). The chamber contains 2 bladders; 1 is connected to the roller pump and the other is connected to a pulsatile bypass pump (Model 20, Kontron Cardiovascular) which provides active compression and decompression of the blood-filled bladder. Arterialized blood from the bladder was pumped in a pulsatile manner through the retroperfusion catheter positioned in the great cardiac vein. A Statham P23 Db pressure transducer was connected between the pumping chamber and the retroperfusion catheter to assist in monitoring venous perfusion pressures. These pressures directly reflect the pressures in the coronary veins. An elevation in pressure may occur due either to wedging of the catheter in the coronary veins or inadequate drainage due to the flow rate being set too high. If the flow was set at >50 ml/min, the retroperfusion pump was usually not able to deliver the required volume during the diastolic compression phase. Consequently flow would continue into the coronary veins during systole, resulting in inadequate drainage and an elevation in pressure. We previously showed

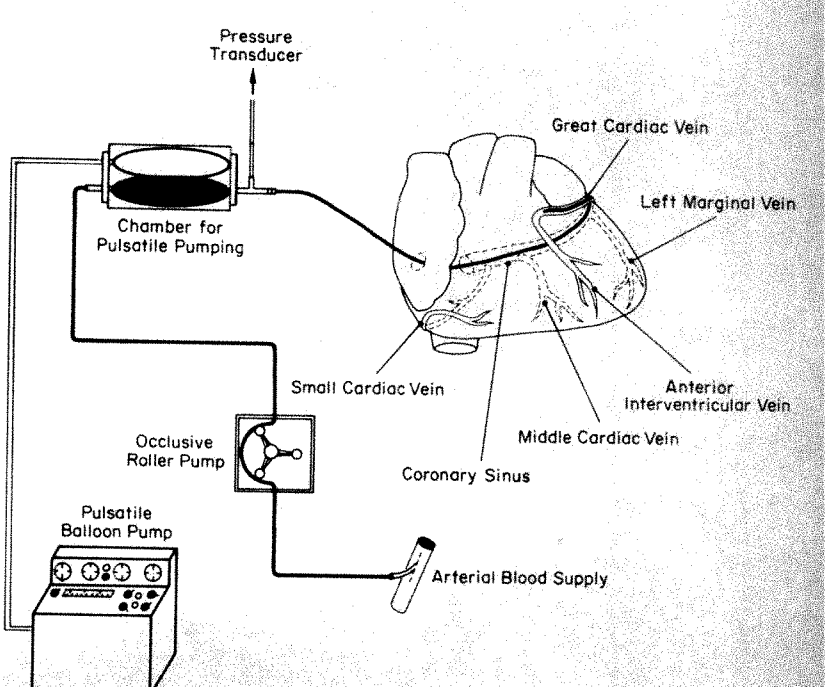

FIGURE 1. Diagram of the retroperfusion system. See text for detailed description.

that a flow rate of 40 to 50 ml/min produced adequate rearterialization.[5] We did not simultaneously record the pressures in the coronary veins as this would have required insertion of a separate line for pressure recording. However, in preliminary experiments, we monitored pressure in the anterior interventricular vein during retroperfusion with flows up to 60 ml/min and found the pressure <50 mm Hg.

The pulsatile pump system was adjusted so that forward pulsed perfusion occurred only in diastole and perfusion was interrupted during systole so that normal coronary venous drainage was allowed. This was accomplished by simultaneously displaying the left ventricular pressure and the retroperfusion pressure tracings so the retroperfusion pulse could be adjusted to occur during the diastolic interval. Anticoagulation was maintained during the period of retroperfusion by initial heparinization (5 mg/kg intravenously), with supplemental intravenous heparin administered to maintain the activated clotting time at 350 to 500 seconds to prevent blood clotting in the retroperfusion system.

Study protocol: An experimental group of 5 baboons underwent coronary venous retroperfusion. Control baseline hemodynamic recordings and epicardial electrograms were monitored for 30 minutes before coronary occlusion. The left anterior descending coronary artery was then occluded, and hemodynamic and electrocardiographic recordings were obtained every 15 minutes throughout the experiment. Coronary venous retroperfusion was initiated after 1 hour of occlusion and maintained through a 4-hour period of coronary artery occlusion. When retroperfusion was ended, anterograde perfusion was simultaneously restored by release of the occluding snare. The retroperfusion catheter was then removed, and protamine sulfate was administered to return the activated clotting time to the control level. After a 1-hour reperfusion monitoring period, the epicardial electrodes as well as the cardiac output and left ventricular pressure catheters were removed. The chest was closed while monitoring arterial pressure and the electrocardiogram. The remaining indwelling lines were then removed and the baboons returned to their cages. At 24 hours after occlusion the baboons were killed by rapid infusion of a saturated solution of potassium chloride and their hearts were excised for histologic analysis.

A control group of 5 baboons underwent an identical protocol to that utilized in the experimental group including placement of the coronary venous retroperfusion catheter and heparinization. In this group, however, no retroperfusion was initiated. Anterograde reperfusion was restored after 4 hours of coronary occlusion.

Perfusion bed delineation and histologic assessment: Cannulas (0.58 mm internal diameter) were placed into (1) the left anterior descending coronary artery at the site of previous occlusion, (2) the proximal left anterior descending artery, (3) the proximal left circumflex artery, and (4) the proximal right coronary artery. These arteries were then injected simultaneously and at equal flow rates with colored silicone rubber microvascular dyes (Microfil, Canton Bio-Medical Products, Boulder, Colorado) which readily pass through the capillary beds.[7] We previously showed that this dye injection technique allows accurate delineation of the perfusion bed subserved by an occluded coronary artery.[8] After fixation of the hearts in 10% formalin for 3 days, serial cross-sections of the left ventricle were made at 3 mm intervals parallel to the minor axis. A microscopic slide was made from each cross-section and stained with hematoxylin and eosin. The perfusion bed of the occluded artery was clearly visualized on the paraffin tissue block of the left ventricular cross-section and was marked on the corresponding histologic slide by superimposing the slide on the tissue block. Microscopic examination of each histologic slide allowed the area of infarction to be also marked on the slide. The areas of the perfusion bed and the areas of infarction were determined by planimetry. These areas were multiplied by the thickness of each cross-section to give the respective volumes for each section. Summation of the volumes of each tissue section yielded the total volume of the perfusion bed and the total volume of infarction for each heart. These values were multiplied by the tissue density to yield the mass of the perfusion bed and the mass of infarct.

Statistical analysis: The significance of hemodynamic and histologic changes between control and retroperfused baboons was examined using Student's t test. All values are given as mean ± standard error of the mean.

Results

After occlusion of the left anterior descending coronary artery in all 10 baboons, a discrete area of the anterior left ventricular wall appeared visibly cyanotic. In the retroperfused baboons, with the initiation of coronary venous retroperfusion, the anterior interventricular vein was visibly arterialized, and resolution of the area of ventricular cyanosis occurred. With release of the occluding snare 4 hours after occlusion, rearterialization occurred promptly in the previously occluded coronary artery in all baboons.

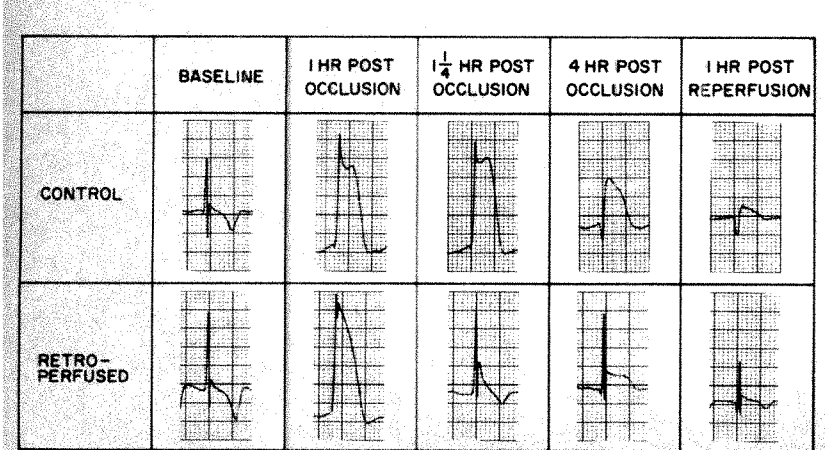

FIGURE 2. The progression of electrocardiographic changes during the periods of occlusion and reperfusion are shown for a representative control baboon and a retroperfused baboon. No significant S-T segment elevation was present before occlusion in either baboon. One hour after occlusion there were markedly elevated S-T segments in both the control and retroperfused baboons. At 1 1/4 hours after occlusion (15 minutes after the initiation of retroperfusion), there was a significant reduction in S-T segment elevation in the retroperfused baboon with no significant change in S-T segment elevation in the control nonretroperfused baboon. Four hours after occlusion, immediately before reperfusion, the S-T segment in the control baboon remained elevated while the S-T segment in the retroperfused baboon was near baseline. One hour after reperfusion, the control baboon had lost most of its R-wave amplitude and developed a Q wave while the retroperfused baboon retained significant R-wave amplitude and did not develop a Q wave.

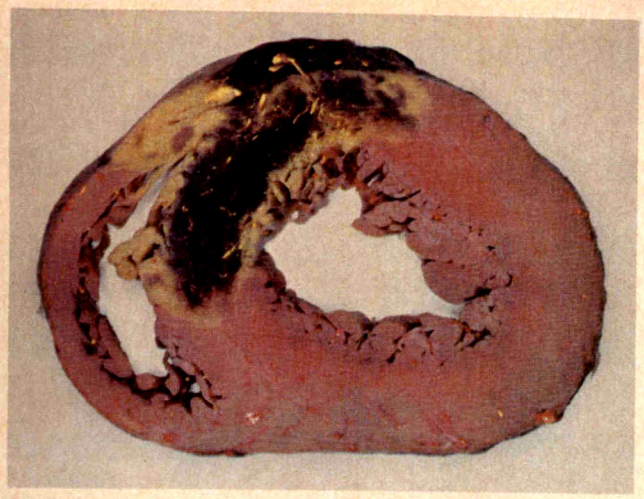

FIGURE 3. Representative cross-section of the heart from a control baboon with a 4-hour occlusion of the left anterior descending coronary artery followed by reperfusion. The perfusion bed of the previously occluded artery was injected with yellow microvascular dye and the adjacent perfusion beds with red dye. The perfusion bed of the occluded artery is readily delineated and contains a large hemorrhagic region which occupies virtually the entire perfusion bed.

Epicardial electrocardiographic recordings: The progression of electrocardiographic changes during the periods of occlusion and reperfusion for a representative control and retroperfused baboon are shown in Figure 2. There was no significant S-T segment elevation in any of the epicardial leads in either group immediately before occlusion. S-T segment elevation occurred in epicardial leads in the area of ventricular cyanosis within minutes after occlusion of the left anterior descending coronary artery. In the retroperfused baboons, S-T segment elevation decreased rapidly to near control values after the initiation of coronary venous retroperfusion. In the control group, S-T segments remained elevated throughout the 4-hour period of occlusion. In both groups, the remaining S-T segment elevation steadily decreased during the 1-hour period of anterograde reperfusion, although S-T segments sometimes remained slightly elevated in the control baboons.

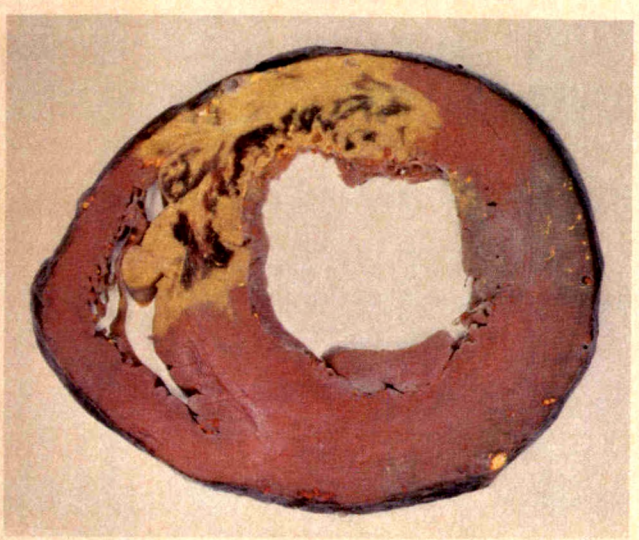

FIGURE 4. Representative cross-section of the heart from a retroperfused baboon. Retroperfusion was iniitated 1 hour after occlusion of the left anterior descending coronary artery and maintained for a 4-hour period of occlusion followed by reperfusion. The perfusion bed of the occluded artery is readily delineated by the yellow dye and contains patchy areas of hemorrhage in the subendocardial and mid-wall regions.

Delineation of the perfusion bed of the occluded coronary artery: Cross-sections of the left ventricle in both control and retroperfused baboons showed the perfusion bed of the occluded coronary artery to be readily delineated by the microvascular dye. A representative cross-section of the heart from a control baboon, shown in Figure 3, demonstrates the distinct demarcation of perfusion bed boundaries as well as the extensive hemorrhage which occupied virtually the entire perfusion bed of the occluded artery. Figure 4 shows a representative cross-section of the heart from a retroperfused baboon and again illustrates the distinct demarcation of the perfusion bed boundaries. In contrast to the control group of baboons, however, hemorrhage was confined to the subendocardial and mid-wall regions of the perfusion bed.

Comparison of histologic changes in control and retroperfused baboons: Microscopic examination of hematoxylin and eosin-stained left ventricular cross-sections in control baboons showed extensive coagulation necrosis which essentially occupied the entire perfusion bed of the occluded artery. The area of infarction was completely contained within the perfusion bed. Necrotic myocardial cells exhibited the characteristic changes of pyknosis, karyolysis, and loss of cross-striations. There was extensive hemorrhage within the infarcted region.

Microscopic examination of left ventricular cross-sections in the retroperfused baboons showed that the area of infarction was also completely contained within the perfusion bed of the occluded artery. Infarcts characteristically consisted of a central confluent zone of infarction surrounded by a peripheral zone of small foci of patchy infarction. The infarcts showed coagulation necrosis and involved the subendocardial and mid-wall regions of the perfusion bed, while myocardial preservation was observed in the subepicardial and lateral regions. Hemorrhage was evident within the central area of infarction; however, no hemorrhage was observed outside the infarcted region. In the retroperfused baboons, minimal venous hemorrhage was often evident close to veins at the epicardial surface and particularly those close to the retroperfusion catheter. This hemorrhage did not extend below the epicardial surface. There was no gross evidence of damage to the coronary veins in either group of baboons.

Comparison of the percentage of the perfusion bed infarcted in control and retroperfused baboons: Table I shows the mass of the perfusion bed, the mass of the infarct, and the mass of hemorrhage for individual

TABLE I Comparison of Data on the Control and Retroperfused Baboons

Baboon	Perfusion Bed Mass (g)	Infarct Mass (g)	% of Perfusion Bed Infarcted	Hemorrhagic Mass (g)	% of Perfusion Bed Hemorrhagic
			Control		
1	25.3	23.7	93.6	18.2	71.9
2	15.1	13.8	91.9	8.7	57.6
3	14.3	13.7	95.5	8.5	59.2
4	19.3	18.7	96.5	14.6	75.4
5	15.4	14.3	92.8	8.4	54.2
	17.9 ± 2.0	16.8 ± 2.0	94.1 ± 0.9	11.7 ± 2.0	63.7 ± 4.2
			Retroperfused		
1	40.7	20.3	49.9	8.6	21.0
2	4.7	2.8	58.1	0.1	1.0
3	11.7	6.4	52.8	0.0	0.0
4	16.8	11.1	70.1	2.6	15.7
5	9.9	5.5	55.9	1.1	11.3
	16.8 ± 6.3	9.2 ± 3.1	57.4 ± 3.5*	2.5 ± 1.6*	9.8 ± 4.1*

* Significant difference ($p < 0.001$) between control and retroperfused groups.

baboons in both groups. A substantial reduction was observed in the percentage of the anatomic perfusion bed infarcted in the retroperfused baboons when compared to that in the control nonretroperfused baboons. The mean perfusion bed mass was 17.9 ± 2.0 g in the control baboons and 16.8 ± 6.3 g in the retroperfused baboons. These values are not statistically different ($p > 0.1$). In the control group, the mean percentage of the perfusion bed infarcted was 94.1 ± 0.9. In the retroperfused group, the mean percentage of the perfusion bed infarcted was 57.4 ± 3.5. This difference was highly significant ($p < 0.001$). Hence, with retroperfusion begun after 1 hour of coronary occlusion, the area of the perfusion bed undergoing ultimate infarction was reduced by a mean of 36.7% when comparing the control and retroperfused groups.

Hemorrhage was always contained within the infarct region and the mean percentage of the perfusion bed that was hemorrhagic was significantly lower than the mean percentage of the perfusion bed infarcted in both control and retroperfused groups ($p < 0.001$). In the control group, the mean percentage of the perfusion bed that was hemorrhagic was 63.7 ± 4.2; in the retroperfused group the mean percentage of the perfusion bed that was hemorrhagic was 9.8 ± 4.1. This difference was also highly significant ($p < 0.001$).

Hemodynamic changes: Table II summarizes the hemodynamic values in the control and retroperfused baboons for the preocclusion, 15-minute postocclusion, 4-hour postocclusion (before ending retroperfusion), and 1-hour postreperfusion recording periods. At the preocclusion recording period, there was no significant differences in any of the hemodynamic values in control and retroperfusion baboons. There were no significant changes from the preocclusion recording period in any of the hemodynamic values in the control or retroperfused groups at any of the recording periods.

Discussion

The coronary veins have been utilized as a means of rearterialization of a region of myocardial ischemia since the initial experimental and clinical observations of Beck et al[9,10] and others.[11,12] The concept of selective rather than global coronary venous retroperfusion, to-

TABLE II Hemodynamic Values Before and After Occlusion and After Reperfusion for the Control and Retroperfusion Baboons

		Before Occlusion	After Occlusion		1 Hour After Reperfusion
			15 Minutes	4 Hours	
HR (beats/min)	Control	124 ± 4	128 ± 6	125 ± 4	124 ± 5

$\overline{AP}$ = mean arterial pressure; CO = cardiac output; HR = heart rate; LVEDP = left ventricular end-diastolic pressure; peak dP/dt = peak value of rate of rise of left ventricular pressure.

gether with the identification of a group of patients with severe chronic arterial disease not amenable to coronary bypass grafting, led to surgical procedures aimed at selective arterialization of the coronary venous system.[13–17] Subsequently, several investigators modified this concept and employed retroperfusion by selective catheterization of the coronary venous system to reverse ischemia following acute coronary artery occlusion.[1–4,18] These systems have employed pulsatile venous retroperfusion which is synchronized with the cardiac cycle, so that the retrograde arterial pulse is programmed to occur during diastole and is discontinued during systole to allow for adequate venous drainage. These studies have demonstrated that after the initiation of retroperfusion, there is (1) a reduction in epicardial S-T segment elevation,[1,3,4,18] (2) improved myocardial oxygen tension in the ischemic segment,[3,4] (3) improved function in the ischemic segment,[2,4] and (4) an increase in global left ventricular function.[1,2] However, despite these favorable reports, little information has been generated to document the extent to which retroperfusion may decrease ultimate histologically determined infarct size. Therefore, the present study evaluated the effectiveness of retroperfusion in reducing infarct size when begun 1 hour after occlusion and maintained throughout a total 4-hour period of coronary occlusion. Additionally, infarct size was related to the size of the anatomic perfusion bed of the occluded artery (region at risk to infarction) for a more accurate assessment of the effects of retroperfusion on infarct size.

Quantitative method of determining myocardial salvage due to coronary venous retroperfusion: It has been shown considerable variability exists in infarct size resulting from coronary artery occlusion at any given anatomic site.[19,20] This variability results from differences in the region at risk to infarction due to inherent differences in the size of the anatomic perfusion bed subserved by an occluded artery. We have previously demonstrated in the baboon that the microvascular dye technique employed in this study accurately delineates the anatomic perfusion bed of the occluded artery.[8] By comparing the percentage of the perfusion bed of the occluded artery which undergoes infarction in control and retroperfused baboons, an accurate quantitative assessment of the degree of myocardial salvage achieved by retroperfusion may be determined.

Effectiveness of coronary venous retroperfusion in reducing infarct size: We previously demonstrated in the baboon that retroperfusion started at 15 minutes after coronary occlusion and maintained for a total 4-hour period of occlusion resulted in an 84% mean reduction in infarct size.[5] Because retroperfusion was initiated early, before the onset of necrosis within the ischemic region, the optimal effectiveness of retroperfusion was demonstrated in the study. In the present study, retroperfusion was begun 1 hour after occlusion and resulted in a 36.7% mean reduction in infarct size. Thus, the delay from the onset of coronary occlusion to the initiation of retroperfusion is a critical determinant of the degree of myocardial salvage.

Comparison of anterograde arterial reperfusion versus coronary venous retroperfusion in reducing infarct size: The degree of myocardial salvage with anterograde arterial *reperfusion* depends on the time reperfusion is begun. The degree of myocardial salvage with *retroperfusion* depends not only on the time retroperfusion is begun, but also on how effectively the retroperfusion system is capable of delivering arterial blood to the ischemic region. Thus, it is interesting to examine how closely coronary venous retroperfusion approaches the effectiveness of arterial reperfusion in reducing infarct size.

In order for coronary venous retroperfusion to be effective, it must deliver sufficient arterial blood to all levels of the myocardial wall within the ischemic region to satisfy the oxygen demands of this region. A number of studies using injection of various contrast agents have indirectly suggested that retroperfused blood is effectively delivered to the ischemic region.[21,22] The studies of Hochberg et al[16,23] using radioactive microspheres demonstrated that retrograde arterial blood flow is distributed to all levels of an acutely ischemic region and not significantly shunted by thebesian or veno-venous channels. More recently, Berdeaux et al,[18] also using microspheres, demonstrated that retroperfusion initiated at 1 hour after coronary occlusion returned transmural flow in the ischemic region to 45% of the normal control flow which existed before coronary occlusion. The results of this study of Berdeaux et al[18] bear directly on the question of whether this degree of restoration of flow is sufficient to substantially prolong myocardial viability.

This question may be clarified by directly comparing the degree of infarct salvage achieved by anterograde reperfusion with the degree of infarct salvage achieved by retroperfusion instituted at comparable times after acute coronary occlusion. We have shown in the baboon that with anterograde reperfusion 2 hours after coronary occlusion, a mean of 50.1% of the perfusion bed of the occluded artery was infarcted.[24] With retroperfusion 1 hour after coronary occlusion in the present study, a mean of 57.4% of the perfusion bed of the occluded artery was infarcted. It is interesting that with retroperfusion 1 hour after coronary occlusion, the percentage of the perfusion bed infarcted was approximately the same as that found with anterograde reperfusion 2 hours after occlusion. This finding is consistent with the observation by Berdeaux et al[18] that retroperfusion initiated 1 hour after coronary occlusion was capable of restoring blood flow to only 45% of the normal control flow.

Hemorrhage associated with retroperfusion: Is hemorrhage associated with retroperfusion deleterious to ischemic myocardium? Although the infarcts in the retroperfused baboons were hemorrhagic, the hemorrhage was confined within the infarcted region and did not appear to extend the infarct. This observation is similar to that noted with anterograde reperfusion; several investigators have demonstrated that hemorrhage after reperfusion does not extend infarct size.[25–28] Some hemorrhage was noted around superficial veins,

but it did not extend below the epicardial surface and there was no gross damage to the coronary veins.

Clinical application of coronary venous retroperfusion: Experimental animal studies suggest that anterograde reperfusion must be undertaken within the first few hours after coronary occlusion for significant salvage of ischemic myocardium to occur.[24,25,29] The time interval in the clinical setting in which restoration of perfusion salvages significant myocardium remains unclear but may be longer than experimental animal studies suggest. Hence, retroperfusion may be useful clinically as a simple and prompt method to temporarily rearterialize an acutely ischemic region until such time as more definitive revascularization may be undertaken. It is also noted that coronary venous retroperfusion may be useful by providing a potential avenue for the introduction of pharmacologic agents directly into the ischemic region.

Introducing the Pacesetter Model 388
Programming/Telemetry System

The Features.

Multiprogrammability. The Model 388 System enables the physician to program all Programalith® pulse generators in a wide range of values for up to six parameters, including, with Programalith III, the option of programming the pulse amplitude to 7.5 volts.

Programmed (stored) telemetry data. Allows the physician to determine what the implanted device *should be doing*, on all programmable parameters.

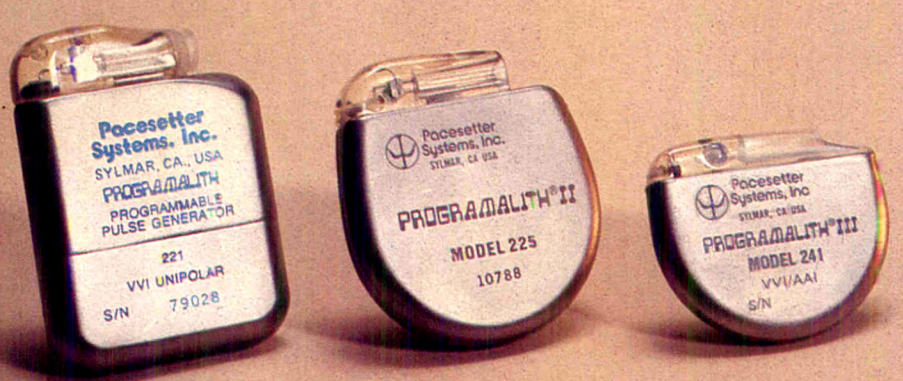
Measured telemetry data. Provides data on what the device *is actually doing* on all components of the system, including the pulse generator, the battery, and the entire lead system.

Telemetry of intracardiac electrograms. An invaluable aid for the physician that yields electrogram morphology and timing information, which can be used as additional diagnostic tools.

Simple clinical utility. The Pacesetter Model 388 Programming/Telemetry System may be the easiest to use and understand. In addition to the visual screen display, a hard copy record of each interrogation and/or programming session is provided for your patient's permanent file.

The Model 388 is *one* device consisting of the printer base and the programmer module, which can be detached for portable, hand-held convenience.

Compatability. The Model 388 Extended Programming/Telemetry System allows multi-parameter programming with three types of telemetry information for all Programalith pulse generators, in both single- and dual-chamber configurations: Programalith I, Programalith II, and Programalith III.



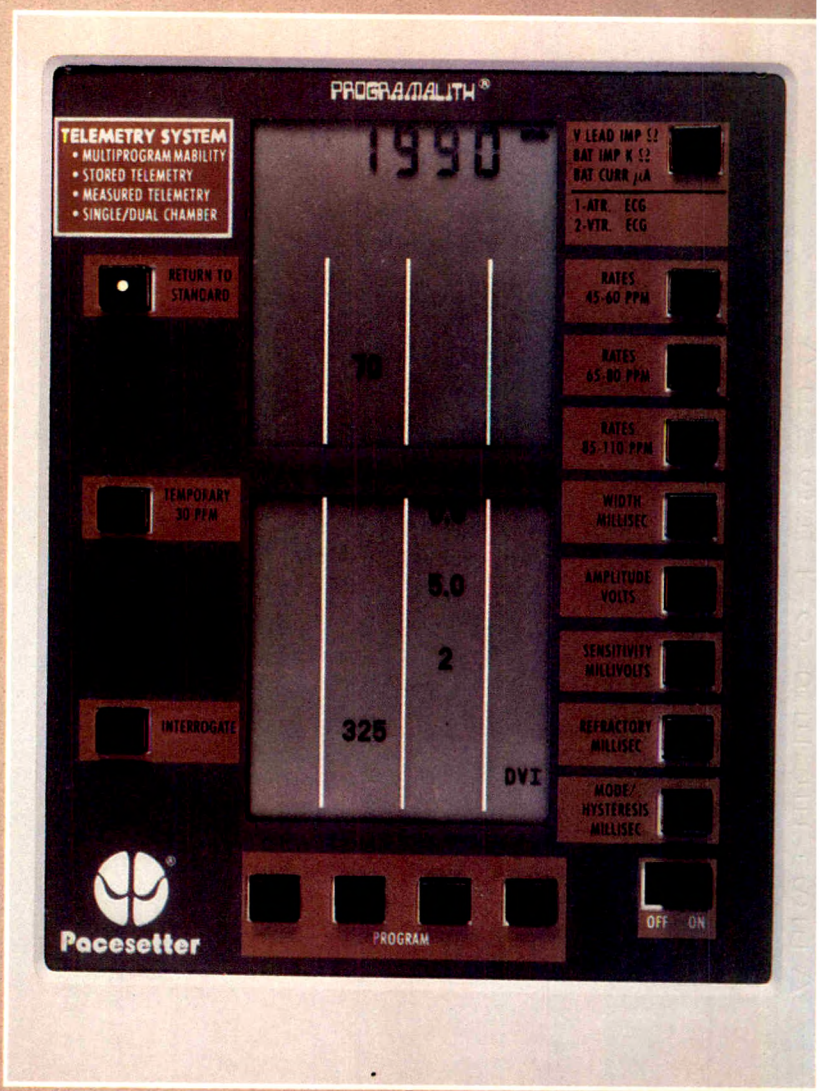
Pictured left: Programalith I, Programalith II and Programalith III.

Pacesetter expands it telemetry system– and our commitment

The Commitment.

The Pacesetter Programalith® system, the world's first with functional bi-directional telemetry, has been the leading example of advanced pacemaker technology since its introduction. Now, with the introduction of the Pacesetter Model 388 Extended Programming/ Telemetry System, that technology –and that leadership—have been expanded.

Perhaps most important of all is the unique design concept behind the Model 388, which provides more telemetered data retrieval from newer Pacesetter pulse generators, and retrieves additional telemetry information from previously implanted Programalith models. This concept—that our research and development efforts be applied to existing products as well as to new products—is at the heart of Pacesetter's commitment.



The Programalith A-V pulse generator, shown actual size. Readout on faceplate of Model 388 Programming/ Telemetry System, illustrating display of telemetry data, with no lead in pulse generator.

Tribute to Paul Wood

E. GREY DIMOND, MD

We were at morning report and the residents and senior medical students were gathered. A young patient with atrial fibrillation had been admitted during the night. The episode had begun suddenly and had never occurred before. The resident expressed surprise at the amount of urine the patient had passed since admission and said, "We will work him up for heart failure and diabetes." Without guile, I said, "But isn't this a classic example of the polyuria with lone fibrillation that Wood described?" There was silence, and then from the back of the room a hesitant voice asked, "Who's Wood?"

I laughed, not quite sensing the dimension of the query, and asked if someone would look up the reference and tell us about it the next morning. Morning report ended, and the senior resident sought me out, with pen in hand. He said, "Where do I find this Wood reference? What journal is it in? Where is he?" The senior resident was sincere and I told him to go to the *British Heart Journal* of the early 1960s. He whistled in surprise that this was indeed a historical source.

The next morning, we began morning report by my comment and query: "Yesterday we talked over the case of a young man with an episode of atrial fibrillation and diuresis. Our senior resident will give us a report on his review of the literature. Before he does, I want to ask 3 questions so we can all know our shared information base." I asked for a show of hands of those present who used the term "lone" atrial fibrillation (no hands), those who had heard of Dr. Willie Evans (no hands), those who had heard of Paul Wood (one hand—that of the resident I had sent to the library). There were 16 residents present, from 11 medical schools.

This experience was in the spring of 1982, and I mulled, thought, reflected, and sighed for several days. I pulled out the 2 articles, just to be sure that my memory was valid: "Lone Auricular Fibrillation," by W. Evans and P. Swann, *British Heart Journal* 1959;16:189; and "Polyuria in Paroxysmal Tachycardia and Paroxysmal Atrial Fibrillation," by Paul Wood, *British Heart Journal*, 1963;25:273.

So, these articles did exist; it was not all a mirage of things past. However, my attention was caught by the footnote on Wood's article of 1963. Maurice Campbell, then the Editor of the *British Heart Journal*, had added a note that he had edited this article for Paul Wood, and it was published posthumously.

I paused, as if I had felt a gentle shock. I suddenly remembered that 1962 was indeed the year of Wood's death—and my conversation with the residents was occurring within a few months of the 20th anniversary of his death. The oldest of the residents would have been 6 or 7 years old when Wood died.

For the next several days a lingering sadness weighed on me. I pulled down from my shelf his book and also the memorial that his friends had written on the 10th anniversary of his death. I read these, and it was vivid again what a dynamic force he had been in the world of cardiology. Others did the great surgical feats or brought forth new technical procedures, but one man alone was the talent who absorbed the potential of the new tools of catheter, angiography and phonocardiography, tamed them, and showed how a clinician could frame their messages into clinical algorithms.

Wood came back from the War and by January 1950 had accomplished the intellectual feat of bringing technique and clinical skills together to define a new kind of dynamic cardiology. His book was at once a physiologic statement of his clinical mastery, and a flag to all the world that there was a new leader in diagnostic cardiology, and he was in London and his name was Paul Wood.

To grasp the sheer energy involved, one must remember he was born in India, raised in Tasmania, schooled in Australia, house officered in New Zealand, and gave 5 years to military service; but this book and the enormous clinical and laboratory experience behind it was accomplished by age 43. If one credits Paul White's classic text with establishing the dimensions, the vocabulary, and almost the definitions of cardiology; and Friedberg's book with expressing a single physician's clinical experience within these parameters; then Wood's book was the landmark in print announcing the new era of physiologic, morphologic, dynamic cardiology. It was a point in time, gathering together the vast data accumulated from laboratories and autopsies, giving it a bedside logic, and making it possible for the bedside clinician to define the altered anatomy and physiology which the cardiac surgeon would face. In a certain sense it, this book created the era of aggressive intervention in cardiology.

Wood's colleague, Evan Bedford, expressed this sentiment exactly in words written after Wood's death: "The publication of his textbook . . . in 1950 was a great achievement after absence on war service abroad, and had the same profound influence on cardiology as Paul White's book had 20 years earlier. It reflected Wood's personal teaching, based on the meticulous analysis of his own cases. . . . From the moment I first perused the book, I realized that it was a masterly exposition . . . and it quickly became a best-seller."

Paul Wood's "Preface," dated January 1950, is but 1 page long, and if my Editor would permit, I would offer it as the single illustration of this article. However, the last paragraph

From the School of Medicine, University of Missouri-Kansas City, Kansas City, Missouri.

Address for reprints: E. Grey Dimond, MD, School of Medicine, University of Missouri, Kansas City, Missouri 64108.

must be quoted, for it was *the* Paul Wood message—a message that 20 years has made even more imperative to repeat: "In presenting this book I have attempted to maintain a proper balance between man and his instruments, between experienced opinion and statistics, between traditional views and the heterodox, between bedside medicine and special tests, between the practical and the academic; and so link the past with the present."

His book of 1950, and its second revised edition of 1952, did just what he stated as his purpose. Now there are 3 large textbooks of English language cardiology, all American, and all assembled from a large cuvée of cardiologists. For 20 years no one has again attempted to do what Wood did, and perhaps no one should. In 1950 he brought together the essence of bedside cardiology and defined a relationship between altered morphology and the laboratory methods which had poured a flood of data and formulas. In the 20 years since his death, the torrent of new technology has fragmented cardiology, so perhaps no one again will in a single person encompass both exquisite clinical skill and mastership of all the hardware.

The year he died, he came to the United States as the honored overseas guest of the American College of Cardiology. I was its president that year, and he and I had 7 special days together. The date was mid-June 1962, and we talked of our futures. He was gravely concerned about what he should, or could, do with the remaining years of his career. He said he knew he had made a real contribution in making the work from the laboratory clinically useful. He could not see himself taking on the new era of biochemistry, muscle physiology, and electronic instrumentation. He believed that was for the next generation of physicians. He was, he said, like a boxer who has won but now knows it's time to stop, but the momentum of his followers forces him on. We talked, shared, planned, agreed—and the next month he was dead.

He died at age 54, just 12 years after the publication of his book. If he had lived, he would now be but 74—the right age for tapering a career, and therefore one could say he died too young and he was denied the pleasure and honors these 20 years would have brought him. Maudlin it may be, but I don't believe he would have felt that way. The author of Wood's obituary in the *British Medical Journal*, written in 1962, caught this same feeling: "One suspects now, knowing all the facts, that P.W. would not have been critical of his own lot, and he would have discounted any tragedy in it." That was written by Walter Somerville, who knew Wood well and also was his physician from the hour of his attack until his death, within the week.

A great tradition of Medicine is the honoring of our predecessors. Such a tradition kept itself alive naturally and easily in the past, when it was impossible to dispute the "experienced opinion" of the older clinician, simply because he had lived longer and seen more—and when precision diagnosis by instrument was not epidemic and technical intervention the norm. It was easier for the elder to maintain his role as a resource for the oncoming young man, when the respected tools of the clinician were experience, time, and seniority. He could command the scene, measuring securely his opinion against that of the younger man.

Today, experience and maturity have eroded rights; the younger man, with his biochemical knowledge, his electronics knowledge, his computers, his pumps, his host of precision instruments, his spider skein of monitoring tubes, can, instead of honoring the old clinician, with deadliness devastate him, making him insecure and timid and, in fact, seize the scene from the patriarch.

We live in an era where experience, judgment, and wisdom do not gain for the older clinician a position of trust, but instead all are too often considered a cover-up for technical obsolescence. And there indeed is the tragedy of modern medicine. The timorous query from the back of the room, "Who's Wood?," said it all. There is no turning back the clock, and an older man risks the corridor asides of house staff suggesting that his seasoned sentiment is but the drawing shade of time. . . . But one wishes that every chief of every medical service had a required showing of the *Jugular Venous Pulse* by Paul Wood. The wisest of the house officers would gain a hint of what is being lost and what were the special abilities of Paul Wood.

The Early Pathophysiologic Understanding of Angina Pectoris

PAUL KLIGFIELD, MD

Caleb Hillier Parry of Bath and Allan Burns of Glasgow formulated explanations of angina pectoris that stand as brilliant early examples of pathophysiologic reasoning. These astute observers proposed the concept that symptomatic ischemic heart disease results from a dynamic imbalance of myocardial energy supply and demand. Their work forms the basis of our traditional understanding of effort-related chest pain in obstructive coronary artery disease.

William Heberden's masterful clinical description of 20 cases of angina pectoris,[1] published in the *Medical Transactions* in 1772, is well known to most physicians. However, it is not well appreciated that within 30 years of his original observations, a pathophysiologic understanding of angina as an imbalance in myocardial energy supply and demand had become clearly formulated by other British clinicians. Although the morbid anatomic association of angina pectoris with obstructive disease of the coronary arteries was first understood clearly by Edward Jenner, dynamic insight into the pathophysiology of myocardial ischemia was first supplied by Jenner's childhood schoolmate, Caleb Hillier Parry, at the end of the 18th century. Ten years after Parry, Allan Burns explained the concept of effort-induced angina as a symptomatic imbalance of cardiac energy supply and demand, by means of experimental analogy to ischemic limb pain occurring during claudication.

Edward Jenner

Although it is clear that John Hunter, perhaps the most eminent English anatomist of the late 18th century, performed the earliest autopsies on patients dying with a history of angina pectoris, it is doubtful that he clearly perceived the relation of coronary obstruction to the disease. Hunter's pupil Edward Jenner, however, became convinced of this association but withheld his opinion from print because he feared it would deprive Hunter, who had progressive angina, of hope of recovery.[2] Jenner, of course, remains best known for his immortal *Inquiry Into the Causes and Effects of the Variolae Vaccinae*,[3] which introduced the practice of vaccination against smallpox and was dedicated to his friend, Caleb Hillier Parry.

Jenner's striking description of remarkable autopsy findings in an early case of angina pectoris was communicated to Parry by letter in about 1785. "My knife struck something so hard and gritty as to notch it," he wrote. "I well remember looking up at the ceiling, which was old and crumbling, conceiving that some plaster had fallen down. But on further scrutiny the real cause appeared; the coronaries were become bony canals." Yet Jenner, whose subsequent experience confirmed the presence of diseased coronary arteries in other cases of angina, did not propose a mechanism to account for this association.

Caleb Hillier Parry

Caleb Hillier Parry and Edward Jenner had been schoolmates in Gloucestershire and remained lifelong friends. Parry received his medical degree from Edinburgh in 1778, and established a successful clinical practice in the ancient city of Bath, legendary for its mineral waters and revitalized by its striking neoclassical architecture in the Palladian style. Parry summarized 18th century understanding of angina pectoris in a slim volume entitled *An Inquiry into the Symptoms and Causes of the Syncope Anginosa, Commonly Called Angina Pectoris* (Fig. 1), published in 1799 but based in part on lectures earlier given before the Gloucestershire Medical Society.[4]

From the Division of Cardiology, Department of Medicine, The New York Hospital-Cornell Medical Center, New York, New York. Manuscript received December 15, 1981; revised manuscript received February 1, 1982, accepted February 11, 1982.

Address for reprints: Paul Kligfield, MD, Division of Cardiology, Department of Medicine, The New York Hospital-Cornell Medical Center, 525 East 68th Street, New York, New York 10021.

Parry was a strong advocate of Jenner's observation that a link exists between obstructed coronary arteries and angina pectoris. In his monograph, Parry was among the earliest clinical observers to propose a pathophysiologic basis for effort-related chest pain, extending Jenner's pathologic observations to a dynamic formulation. In patients with obstructive coronary disease, "though a quantity of blood may circulate through the arteries," he explained, "sufficient to nourish the heart, as appears, in some instances, there may probably be less than what is requisite for prompt and vigorous action." This proposal clearly introduced the concept of variability of cardiac energy demand as a critical factor in the production of symptoms in patients with angina pectoris. "Hence," he continued, "though a heart so diseased may be fit for the purposes of common circulation during a state of bodily or mental tranquillity and of health yet otherwise good, yet when an unusual exertion is required its powers may fail under the new and extraordinary demand." Proposal of this concept by Parry stands as a monumental early example of physiologic reasoning about diseases of the heart.

Allan Burns

Parry's emphasis on the excessive myocardial energy demand underlying expression of symptoms in angina pectoris was amplified and extended by Allan Burns 10 years later. The short career of Burns was both remarkable and tragic.[5] Born in Glasgow, he apparently never completed formal medical studies, but in 1797 became a laboratory assistant to his older brother John,

a prominent Scottish anatomist and demonstrator best known for his work in obstetrics. Despite his lack of formal education, Allan Burns soon established an independent reputation as an anatomist and surgeon, which led in 1804 to an invitation from Catherine of Russia to travel to St. Petersburg to establish and direct a hospital run along Western European lines. This intriguing and prestigious assignment was held for only 6 months, since Burns was obliged to return to Scotland to take over his brother's lecture schedule after John was convicted of body snatching to secure material for his demonstrations. Burns's obligation to his brother may well have been more academic than financial since John, although as a penalty forbidden to teach anatomy, was otherwise allowed to continue his thriving clinical practice of surgery.

Within several years, Allan Burns produced the first comprehensive treatise on cardiology in English, published in 1809 and entitled *Observations on Some of the Most Frequent and Important Diseases of the Heart* (Fig. 2).[6] His text on the heart was written 10 years before the introduction of the stethoscope, and gave careful clinical and pathologic observations on congenital, hypertrophic, and ischemic disease. Burns died of a ruptured appendix 4 years later, at the age of only 32.

Extending Parry's prior work, Burns highlighted the significance of energy supply and demand imbalance in the heart as the pathophysiologic basis for angina pectoris by proposing an experimental analogy that could be verified easily by all clinicians. "If we call into vigorous action a limb round which we have with a moderate degree of tightness applied a ligature," he suggested, "we find then that the member can only support its actions for a very short time; for now its supply of energy and its expenditure do not balance each other; consequently it soon, from its deficiency of nervous influence and arterial blood, fails and sinks into a state of quiescence." Given this easily observed situation of experimental claudication, Burns was then able to formulate an explanation of the origin of anginal pain in patients with diseased coronary arteries. "A heart," he continued, "the coronary arteries of which are cartilagenous or ossified can, like the limb, discharge its functions so long as its action is moderate and equal. When, therefore, the coronary arteries are ossified every agent capable of increasing the action of the heart, such as exercise, passion, and ardent spirits, must be a source of danger."

Historical Development

As occurs with many diseases, the early appreciation of angina pectoris can therefore be seen to have emerged through several discrete stages at the end of the 18th century. The recognition and clinical description of angina are due to Heberden. This was followed by postmortem correlation with coronary artery disease by Jenner, whose work was intimately entwined with that of Hunter, who in turn was both observer and victim of the disorder. And finally, Parry and Burns formulated an understanding of ischemic heart disease as a dynamic imbalance of myocardial energy supply and demand. Their observations stand as brilliant early examples of pathophysiologic reasoning and form the basis of our traditional understanding of effort-related chest pain in obstructive coronary artery disease.

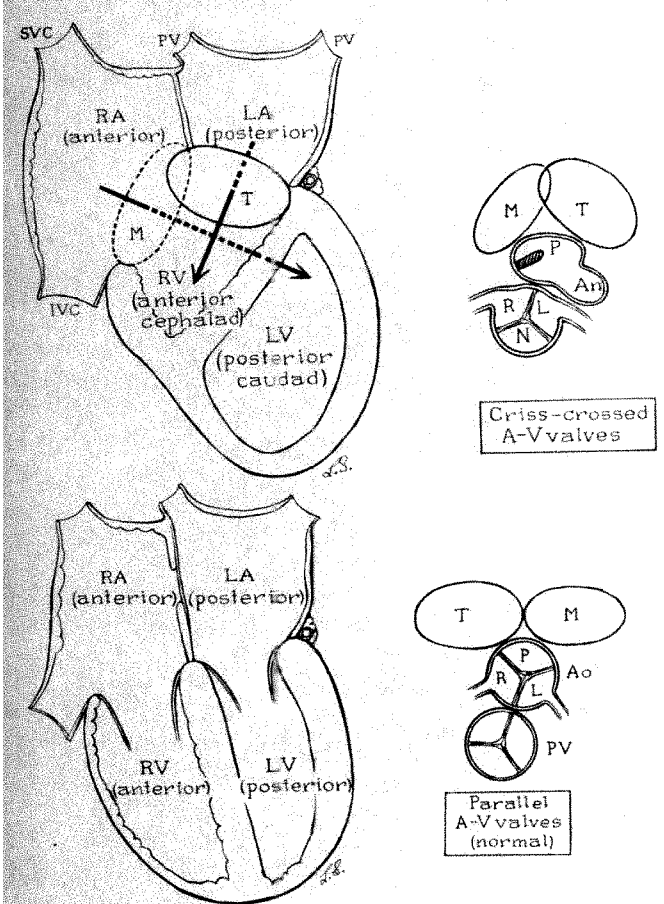
Crisscrossed Atrioventricular Valves and Prolonged Survival

WILLIAM C. ROBERTS, MD, THOMAS L. SPRAY, MD, RICHARD J. SHEMIN, MD, and BARRY J. MARON, MD

Normally, of course, the atrioventricular (AV) cardiac valves have a right-to-left relationship with one another (Fig. 1). The right-sided AV valve connects the right-sided atrium to the right-sided ventricle, and the left-sided AV valve connects the left-sided atrium to the left-sided ventricle. In rare cases, however, the AV valves are not parallel to one another but are crisscrossed, so that the right-sided atrium connects to the left-sided ventricle and the left-sided atrium connects to the right-sided ventricle (Fig. 1). When this occurs, the AV valves have an anteroposterior relation. Since 1974, a number of patients with crisscrossed AV valves have been reported on, and most died early in life from either inadequate or excessive pulmonary blood flow,



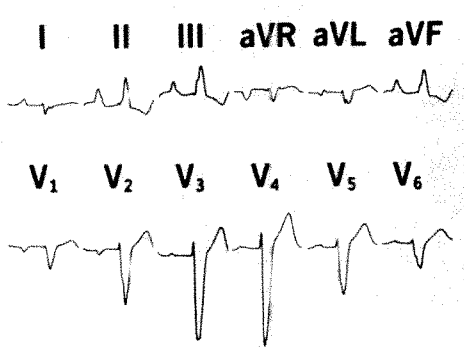


FIGURE 1, left. Diagram showing basic arrangement of the patient's crisscrossed heart (**top**) compared with the normal heart (**bottom**). The valves shown **on the right** are as they appeared after removing the aorta (Ao), pulmonary trunk, and walls of the right atrium (RA) and left atrium (LA). The ventricular septum in the crisscrossed heart is relatively perpendicular to the atrial septum, and this feature allows the crisscrossed valve arrangement. Blood traversing the tricuspid (T) valve from the posteriorly located LA flows anteriorly to the anteriorly located right ventricle (RV) and blood traversing the mitral (M) valve flows posteriorly to the posteriorly located left ventricle (LV). The pulmonic valve (P) (**top only**) is unicuspid and unicommissural, and an aneurysm (An) of its sinus protrudes anteriorly. L = left; N = noncoronary cusp or sinus; P = posterior sinuses of Valsalva of the aortic valve; R = right.

FIGURE 2, top. Electrocardiogram showing intermittent second-degree heart block, left bundle branch block, a P-R interval of 0.21 second, and lack of development of a significant r wave in the precordial leads. V leads ½ standard.

From the Pathology, Surgery, and Cardiology Branches, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted July 2, 1982.

Address for reprints: William C. Roberts, MD, Building 10A, Room 3E-30, National Institutes of Health, Bethesda, Maryland 20205.

the latter by way of an associated large ventricular septal defect. This report was prompted by studying a man who lived 55 years with crisscrossed AV valves associated with double outlet right ventricle and pulmonic valve stenosis.

Although cyanosis and a precordial murmur were present at birth and throughout life, the patient was asymptomatic except on extreme exertion until age 46 years when syncope occurred; cardiac catheterization was performed, and operation refused. At age 54 years (10 months before death), 2,500 ml of blood was removed because of a hematocrit level of about 65%. Two months later, diplopia, a sixth nerve palsy, and intermittent Mobitz II heart block with a left bundle branch block pattern appeared, and cardiac catheterization was repeated. The pressures (in mm Hg) were as follows: pulmonary artery, 15/7; right ventricular outflow, 60/10, and inflow, 135/7; right atrial mean, 5; pulmonary artery wedge mean, 7; left ventricle, 125/10; and aorta, 125/71. Examination 4 months before death disclosed a grade 3/6 precordial systolic murmur with thrill, most prominent at the left sternal border. The electrocardiogram, chest

FIGURE 3. Posteroanterior radiograph (**left**) and lateral angiogram (**right**). The aorta (Ao) arises anterior to the stenotic pulmonic valve. LV = left ventricle; PT = pulmonary trunk; RV = right ventricle.

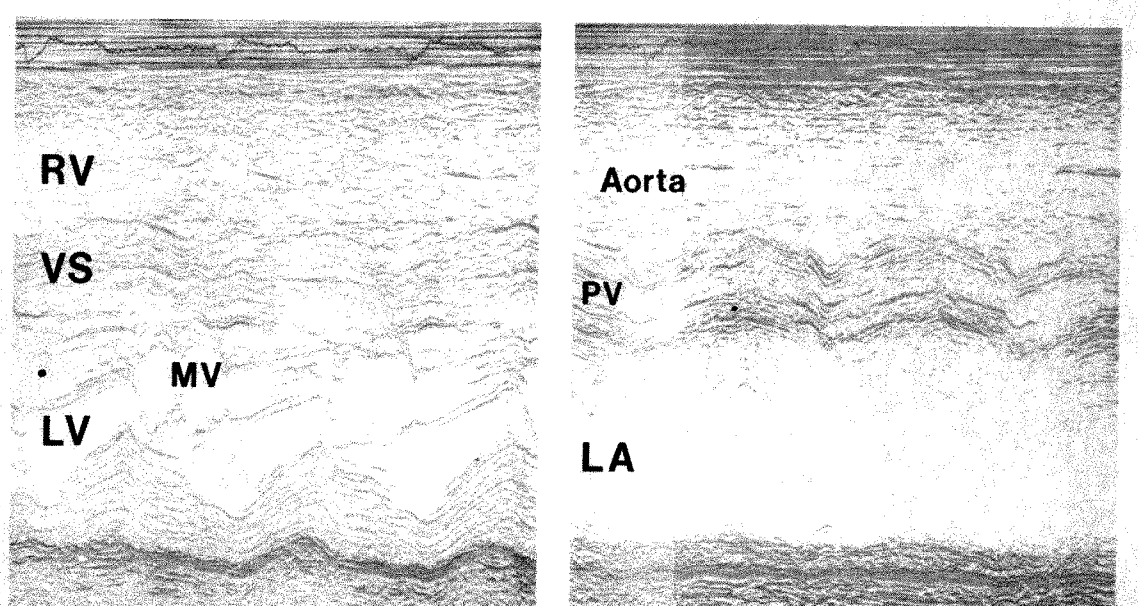

FIGURE 4. M-mode echocardiogram interpreted retrospectively showing (**left**) the mitral valve (MV) to occupy most of the left ventricular cavity (LV), and (**right**) the calcified pulmonic valve (PV) located anterior to the dilated left atrium (LA) and posterior to the aorta. RV = right ventricular cavity; VS = ventricular septum.

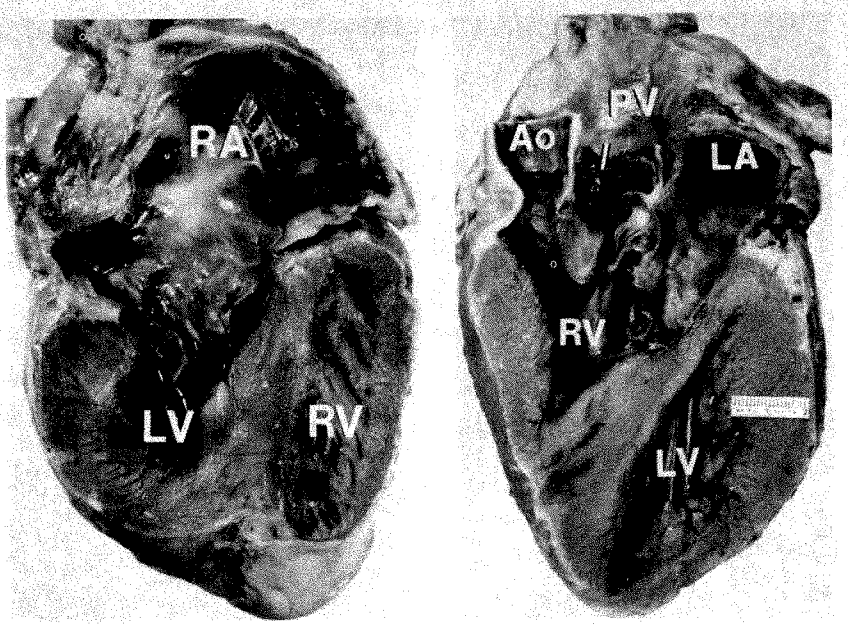

FIGURE 5. Anteroposterior cut of the heart showing (**left**) the right atrium (RA) draining into the left ventricle (LV) and (**right**) the left atrium (LA) draining directly into the right ventricle (RV). Both the aorta (Ao) and the pulmonary trunk arise from the right ventricle. The tricuspid valve is displaced toward the right ventricle, and its leaflets partly obstruct the ventricular septal defect. The conus is inverted. PV = stenotic pulmonic valve.

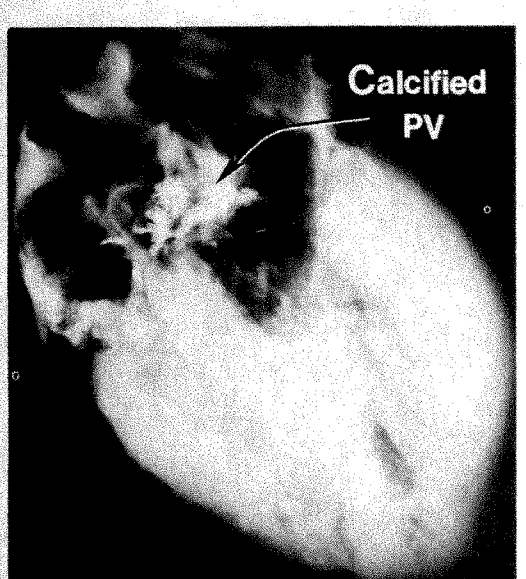

FIGURE 6. Radiograph of heart specimen disclosing heavy calcific deposits in the stenotic pulmonic valve (PV).

roentgenograms, and M-mode echocardiogram are shown in Figures 2 to 4. The right subclavian artery was anastomosed to the right pulmonary artery 70 days before death. Immediately after operation, intractable congestive heart failure developed and 6 days later the Blalock-Taussig shunt was closed; his condition improved briefly, but gradually evidence of poor perfusion of the kidneys, heart, and brain developed and the patient died.

The findings at necropsy are summarized in Figures 1, 5, and 6. The mitral valve, located posterior to the tricuspid

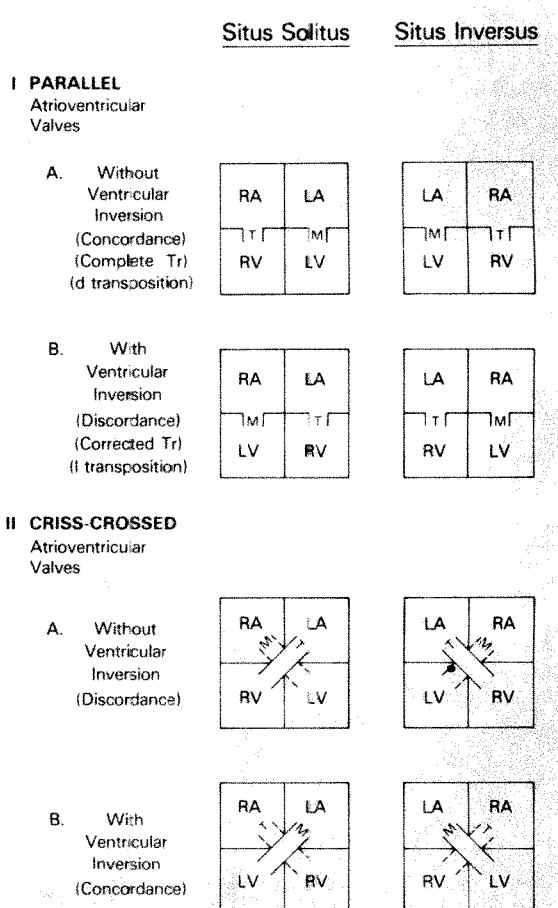

FIGURE 7. Transposition (Tr) of aorta and pulmonary trunk. A proposed classification of transposition complexes including both parallel and crisscrossed AV valves. Abbreviations as before.

valve, connected the right-sided anatomic right atrium to the left-sided anatomic left ventricle, and the tricuspid valve, located anterior to the mitral valve, connected the left-sided anatomic left atrium to the right-sided anatomic right ventricle. The only outlet for blood from the left ventricle was a ventricular septal defect. Both aorta and pulmonary trunk arose from the right ventricle. The pulmonic valve was severely stenotic and heavily calcified (Fig. 6), and a portion of its sinus wall protruded anteriorly (Fig. 1).

This case is by far the oldest reported thus far with crisscrossed AV valves. Of the other 9 necropsy cases reported,[1-6] 4 ([1][Case 13],[2,5][Case 2],[6][Case 7]) died during the first 2 months of life, 1 at 4 years,[3] 2 at 8 years ([1][Case 12],[4]), 1 at 23 years ([6][Case 5]) and 1 at 25 years ([5][Case 1]). Both of the 2 reported patients living longer than 20 years and our patient had obstruction to pulmonary blood flow, a near necessity for prolonged survival with transposition of the great arteries and ventricular septal defect or double-outlet right ventricle.

Nearly all patients with crisscrossed AV valves have malformed or transposed great arteries, the most common being complete transposition and double-outlet right ventricle. Because most present classifications of the transposition complexes assume that the relation of the AV valves to one another is parallel, it is important to delineate this relationship as parallel or crisscrossed because this factor affects intracardiac blood flow and operative therapy[7] (Figure 7).

N-Acetyl Procainamide Causing Torsades de Pointes

BRIAN OLSHANSKY, MD, JAMES MARTINS, MD, and SCOTT HUNT, MD

Torsades de pointes, a distinctive form of ventricular tachycardia (VT) associated with Q-T prolongation,[1] may be caused by antiarrhythmic agents, particularly quinidine. N-acetyl procainamide (NAPA) has not been reported to cause torsades de pointes, but such appears the case in the patient described herein.

A 74-year-old white woman presented with episodes of recurrent VT associated with syncope. At age 69 years (1977) she was treated unsuccessfully for VT with syncope with quinidine gluconate and disopyramide. Cardiac catheterization at the time showed no significant abnormality. In February 1982 all medications were stopped except hydrochlorathiazide (50 mg/day) for systemic hypertension. Monitoring for 1 week demonstrated no arrhythmia. An electrocardiogram showed left-axis deviation and an echocardiogram demonstrated left ventricular hypertrophy. The ejection fraction was 51% by radionuclide angiography. The serum creatinine level was 2.5 mg/dl and the creatinine clearance rate 28 ml/min.

Programmed right ventricular stimulation from 3 sites at 2 basic cycle lengths with 1 and 2 premature stimuli or right ventricular burst pacing did not induce VT. Left ventricular stimulation produced uniform VT with a left bundle branch block, right axis morphology, at a cycle length of 250 ms; this persisted up to 45 seconds and then stopped spontaneously. VT similar to that induced by pacing occurred after 1 dose of oral procainamide (Procan SR) therapy started on February 26. Additional procainamide administered intravenously prevented recurrence of VT associated with plasma levels shown in Table I. On chronic oral procainamide therapy, no further spontaneous VT occurred, but 1 week later VT was still inducible by left ventricular pacing. After an additional 500 mg of procainamide intravenously, however, VT was not inducible with the same pacing protocols (Table I).

On March 5 she was discharged on procainamide, 1,750 mg orally every 6 hours (Table I). On March 11, she returned with frequent episodes of torsades de pointes (Fig. 1) and a markedly longer Q-T interval. Procainamide was discon-

TABLE I Sequential Procainamide (PCA) and N-Acetyl Procainamide Levels

Date	PCA Level (μg/ml)	NAPA Level (μg/ml)	Q-Tc (s)	Condition*
2/26	10.2	15.9	0.39	VT stopped
3/1	7.6	25.2	0.44	VT induced
3/1	10.8	26.7	0.44	VT not induced†
3/5	12.5	28.8	0.40	No VT
3/11	11.1	28.7	0.64	Torsades de pointes
3/11	10.2	30.9	0.64	Torsades de pointes
3/12	4.1	32.8	0.61	Torsades de pointes
3/13	1.1	12.4	0.40	No torsades de pointes or VT

* Condition of the patient when drug level was obtained. † After 500 mg of PCA intravenously.

tinued. Isoproterenol infusion at 1 to 3 μg/min prevented torsades de pointes. About 24 hours later, the apparent Q-T interval remained long (Fig. 2) and torsades de pointes recurred when isoproterenol was stopped. The procainamide level had fallen to levels which previously caused no torsades de pointes, but the NAPA level was still elevated (Table I). The next day when the NAPA level fell, isoproterenol was discontinued without torsades de pointes. The patient was subsequently treated with a combination of diphenylhydantoin (serum concentration 15.4 μg/ml) and quinidine, 300 mg orally every 6 hours (trough serum concentration 2.0 μg/ml) and has had no further episodes of syncope, torsades de pointes, spontaneous VT, or pacing-induced VT. The Q-T interval on diphenylhydantoin and quinidine was normal and she has remained asymptomatic on follow-up.

N-acetyl procainamide, a metabolite of procainamide produced by the liver, has antiarrhythmic potency independent of procainamide.[2-4] Kluger et al[3] reported long-term antiarrhythmic therapy with NAPA. Sudden death occurred in 4 of their patients who had peak NAPA levels ranging from 15 to 66 μg/ml. Although NAPA may prolong repolarization and refractoriness,[4] there has been no proof that it produces arrhythmias or torsades de pointes. The long Q-T intervals and the large U waves associated with high NAPA levels may indicate temporal dispersion of repolarization.

It is possible that a high concentration of PCA or a combination of PCA and NAPA caused the torsades de pointes in our patient. Strasberg et al[5] reported that oral or intravenous procainamide was associated with torsades de pointes. In their patients, VT occurred after administration of 200 to 400 mg intravenously or 3 to 4 g orally per day. No blood levels of either procainamide or NAPA were reported. Our patient had torsades de pointes with a serum NAPA concentration of 32.8 μg/ml and a procainamide concentration of 4.1 μg/ml. In our patient, higher serum procainamide concentrations of 10.2 to 12.5 μg/ml alone or higher total NAPA and procainamide concentrations (Table I) were not associated with torsades de pointes. It is highly unlikely that effects of procainamide lagged behind the

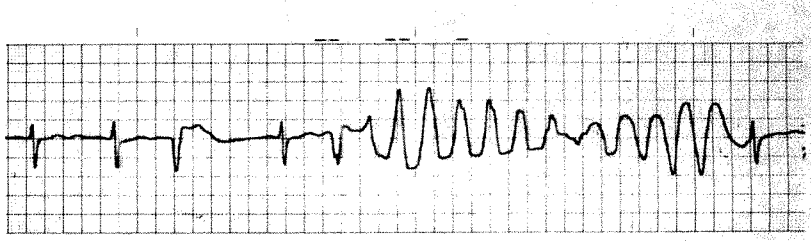

FIGURE 1. Rhythm strip recorded on March 12, 1982 demonstrating a typical episode of spontaneous torsades de pointes which occurred when isoproterenol was stopped. The procainamide level was 4.1 μg/ml and the NAPA level 32.8 μg/ml.

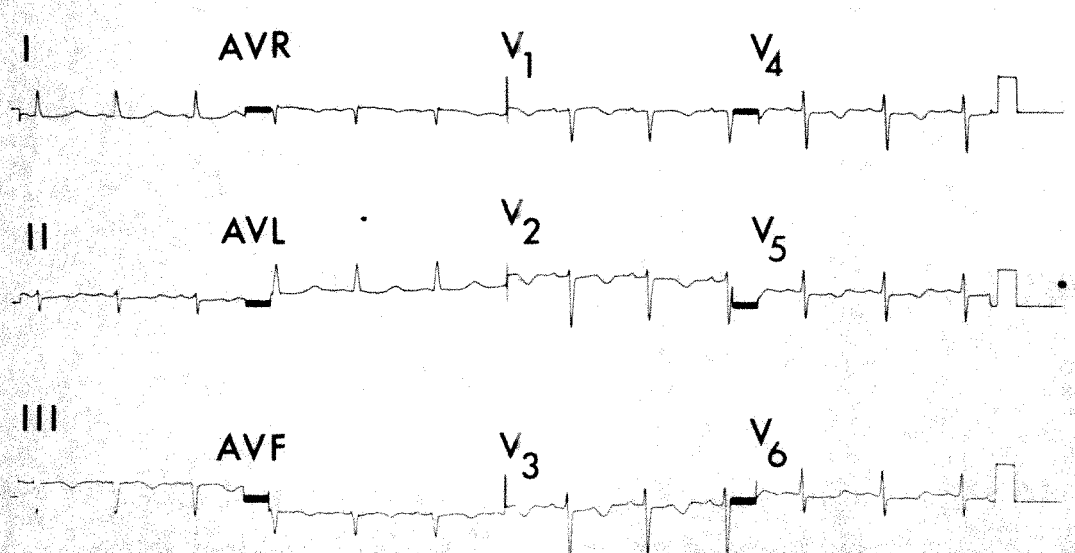

FIGURE 2. Electrocardiogram taken on March 12, 1982 when the procainamide level was 32.8 μg/ml and during isoproterenol infusion, 1 μg/min. Note the long Q-T interval, which may be a fusion of T and U waves, demonstrated best in leads V_4 and V_5.

serum level, particularly since it is reported that arrhythmias in cases of procainamide-induced torsades de pointes cease rapidly after stopping administration of the drug.[5] Therefore, we suggest that the elevated NAPA level was the major cause. In addition, torsades de pointes in our patient was clearly related to serum concentration and was not idiosyncratic.

Thus, elevated NAPA levels may cause torsades de pointes in a patient taking procainamide. Prompt cessation of the drug and temporary isoproterenol therapy or overdrive pacing may be lifesaving.

Extreme Protective Action of Coronary Collateral Vessels In Complete Occlusion of the Left Main Coronary Artery

PAOLO ESENTE, MD, PETER L. ARQUIN, MD, ALESSANDRO GIAMBARTOLOMEI, MD, and GOFFREDO G. GENSINI, MD

The functional significance of the coronary collateral circulation and its role in preserving left ventricular function has been the subject of considerable controversy.[1,2] The case presented here is an example of coronary collaterals protecting virtually all the left ventricular myocardium.

A 52-year-old man had had angina pectoris for 2 years. During the 2 weeks before cardiac catheterization, the frequency and severity of the anginal episodes increased dramatically. Findings on physical examination were unremarkable. Electrocardiograms are shown in Figure 1. At coronary angiography, the left main coronary artery was totally occluded (Fig. 2) and the right coronary artery was narrowed up to 50% in diameter (Fig. 3). The left ventricle was normal on angiography (ejection fraction 65%) (Fig. 4). Aortocoronary grafts were placed to the left anterior descending coronary artery and to the obtuse marginal branch of the left circumflex coronary artery, and 32 months after operation the patient was asymptomatic.

Occlusion of the left main coronary artery, almost invariably associated with left ventricular contraction abnormalities, has been reported by several investigators.[3–5] While rare cases of normal left ventricular function in the presence of a totally occluded left main coronary artery have been reported,[5,6] the association of total left main coronary occlusion, nondominant right coronary artery, and normal left ventricular function

FIGURE 2. Visualization of the left main coronary artery, occluded about 5 mm from the ostium.

FIGURE 3. Visualization of the right coronary artery in the right anterior oblique projection. Several atrial and right ventricular branches originate from the right coronary artery, which is about 50% obstructed (**arrow**). Rich intercoronary collaterals afford visualization of the left anterior descending and the circumflex coronary artery and their branches. The posterior descending branch is given by the circumflex. 1 = right coronary artery; 2 = left anterior descending; 3 = major diagonal branch; 4 = septal branches; 5 = circumflex; 6 = posterior descending.

has not been described previously. The development of adequate coronary collateral vessels is capable of preserving left ventricular function even when the left main coronary artery is totally occluded.

Percutaneous Balloon Valvuloplasty for Pulmonic Valve Stenosis in the Adult

CARL J. PEPINE, MD, IRA H. GESSNER, MD, and ROBERT L. FELDMAN, MD

The management of pulmonic valve stenosis (PS) by surgery is very effective. The recent success of transluminal balloon angioplasty as an alternative to coronary bypass or vascular surgery prompted the application of this principle to a *child* with moderate PS.[1] The early and 4-month follow-up suggested that effective dilatation had been achieved. We performed percutaneous balloon valvuloplasty in an *adult* with severe PS.

A 59-year-old woman who had had a precordial murmur since early childhood did well until approximately 1 year before admission, when fatigue and exertional dyspnea began to markedly limit her activities. She had had vague, probably nonischemic chest pain for several years.

Blood pressure was 160/90 mm Hg, and the pulse rate 80 beats/min and regular. She weighed 245 pounds and stood 60 inches tall. She had a prominent parasternal impulse. A loud pulmonic ejection click was heard at the left sternal border. The S_2 sound was split widely, and a prominent

TABLE I Hemodynamic Findings

	Before Valvuloplasty	Immediately After Valvuloplasty	10 Days After Valvuloplasty
HR	78	80	68
RA	A = 20(15)	A = 12(9)	A = 10(6)
RV_B	160/17	97/10	68/8
RV_I	160/17	65/10	68/8
PA	20/14(18)	23/13(18)	30/15(18)
PAW	(14)	. . .	(15)
LA	(14)	. . .	(13)
SA	160/85(115)	142/75(100)	166/80(114)
CO	4.9	. . .	5.2
A-VO_2 diff	26%	. . .	28%
PVG	(130)	. . .	(30)
PVA	0.3	. . .	1.0

Values in parentheses are mean values. AVO_2 diff = arterial-mixed venous oxygen saturation; CO = cardiac output (liters/min); HR = heart rate (beats/min); LA = left atrial pressure (mm Hg); PA = pulmonary artery pressure (mm Hg); PAW = pulmonary artery wedge pressure (mm Hg); PVA = effective pulmonic valve area (cm^2); PVG = pulmonic valve pressure gradient (mm Hg); RA = right atrial pressure (mm Hg); RV_B = right ventricular body pressure (mm Hg); RV_I = right ventricular infundibular pressure (mm Hg).

systolic thrill was present at the second left sternal border. A grade 4/6 systolic ejection murmur was present. No diastolic murmur was detected. There was no cyanosis, clubbing, or edema.

Electrocardiography showed sinus rhythm with a mean electrical axis of 120°. The R/S ratio in lead V_1 was >1. There were nonspecific ST-T wave changes in the precordial leads. The P wave was prominent in leads II, III, and aVF. Radiography of the chest disclosed cardiac enlargement with a right ventricular prominence. No calcium was present in the pulmonic valve area. Both the pulmonary trunk and left main pulmonary artery were markedly dilated. The hemodynamic findings are summarized in Table I.

During a Valsalva maneuver, injection of indocyanine green into the inferior vena cava disclosed a small right-to-left shunt. A catheter patent foramen ovale was present. Left ventricular cineangiography demonstrated a normal-sized left ventricular cavity and ejection fraction and no regional wall motion abnormalities. Selective coronary angiography showed normal coronary arteries. On right ventricular cineangiography the obstruction appeared limited to the pulmonic valve, which "domed" in systole and "inverted" in diastole. The cusps were thickened but not calcified. Direct measurements from the projected cineangiographic frame revealed the systolic diameter of the pulmonic valve "ring" to be 2.0 cm.

Catheter Design

Based on direct measurements of the valve ring, a catheter was fabricated (Meditech, Watertown, Massachusetts) for use in the pulmonic valve. The catheter was 9 French with a tapered tip and end hole and contained a 20 × 40 mm polyethylene balloon. When inflated by hand at 5 atmospheres of pressure with 10 ml of 50% Renografin® and 50% saline solution, the time from onset of inflation to 90% deflation averaged 8 seconds. Since the distal end of the catheter was tapered for percutaneous introduction and was relatively rigid, the catheter was made for use over an 0.038-inch guidewire to ensure protection of the pulmonary artery.

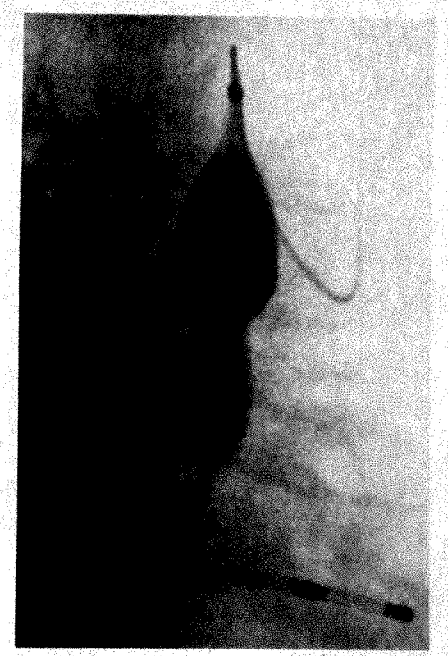

FIGURE 1. Position of the balloon, centered across the stenotic pulmonic valve early during the initial inflation. "Hourglass" configuration of the contrast-filled balloon is created by the stenotic valve. The 0.038-inch J guidewire is in the left main pulmonary artery. After this inflation no reduction in right ventricular systolic pressure occurred (see Figure 2).

Catheter Insertion and Valvuloplasty Technique

Diphenhydramine (50 mg), heparin (5,000 units), and atropine (0.4 mg) were administered. The balloon catheter was inserted without a sheath into the right femoral vein over a 0.038-inch exchange guidewire. This wire had previously been positioned in the left main pulmonary artery using another catheter. Under fluoroscopic and electrocardiographic monitoring, the balloon catheter was advanced to the pulmonic valve region. The location of the balloon was adjusted so that it was positioned across the pulmonic valve. The guidewire was left in place to help stabilize the balloon during inflation and provide a rapid and safe pathway for balloon advancement should hemodynamic deterioration occur during inflation. Right ventricular pressure was monitored from a site below the valve using another catheter. Systemic pressure was monitored from a 5 French catheter inserted percutaneously.

Valvuloplasty was done with constant electrocardiographic, hemodynamic, and fluoroscopic monitoring. The balloon was inflated by hand syringe with 10 ml of 50% Renografin and 50% saline solution. With the initial inflation to 8 ml an indentation, caused by the stenotic valve, was seen (Fig. 1). During inflation there was an increase in right ventricular pressure and a decrease in systemic pressure. Right ventricular and systemic pressures were restored within 6 to 8 seconds after deflation (Fig. 2). After the initial inflation, there was no decrease in right ventricular pressure. This "hourglass" appearance disappeared when the balloon was inflated with 10 ml at 5 atmospheres and the balloon filled

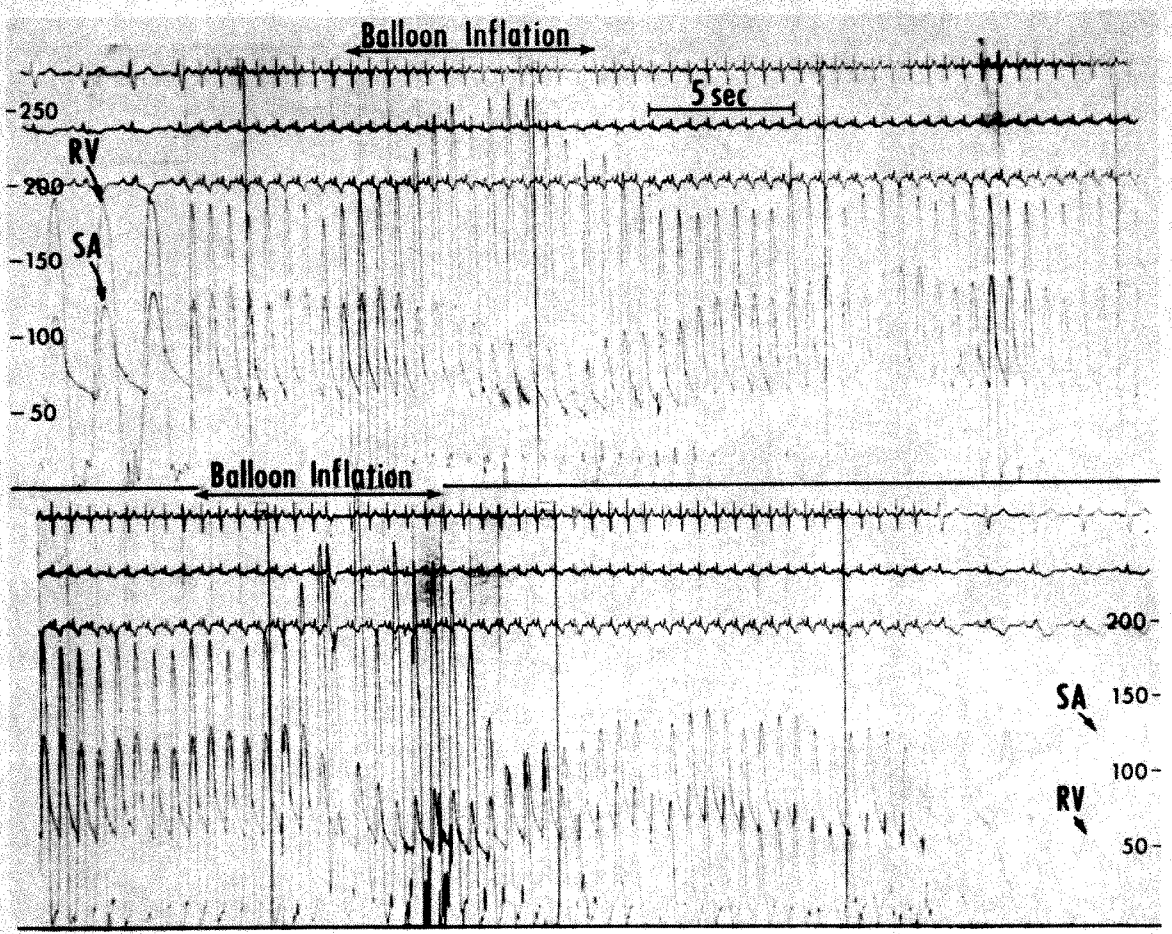

FIGURE 2. Right ventricular (RV) and systemic (SA) arterial pressure recordings before, during, and after balloon inflation. Electrocardiographic leads I, II, and III are shown from top to bottom. **Upper panel,** recordings during initial balloon inflation shown in Figure 1. There was an increase in peak systolic right ventricular pressure and a decrease in systemic arterial pressure as the heart rate increased only slightly. When the balloon was deflated, right ventricular systolic pressure and systemic pressure returned to preinflation values. **Lower panel,** continuous recordings during another inflation-deflation cycle again show elevation of right ventricular pressure with a decrease in systemic pressure. This inflation was associated with a premature ventricular contraction. The balloon distended fully as the indentation from the stenotic valve disappeared (Fig. 3). Shortly after balloon deflation, right ventricular systolic pressure decreased to 68 mm Hg.

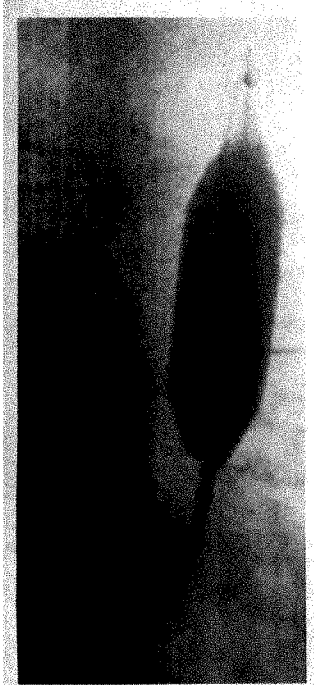

FIGURE 3. Full inflation of the balloon to a diameter of 2 cm.

completely (Fig. 3). This time when the balloon inflated, the increase in right ventricular pressure was associated with premature ventricular contractions (Fig. 2). The patient complained of a fullness in the chest. With deflation, there was a prompt decrease in right ventricular pressure. On pull-back of the pressure monitoring catheter from the subvalvular region, an infundibular pressure gradient was consistently recorded (Table I). For this reason, additional inflations were not performed and the balloon catheter was removed.

Immediately after dilatation there was marked reduction in the intensity of the systolic murmur. The thrill was no longer palpable and the pulmonic ejection sound disappeared. No pulmonic diastolic murmur was heard. She did well and was discharged from the hospital 2 days later. One week after dilatation, she reported marked improvement in effort tolerance. Repeat catheterization studies 10 days after dilatation disclosed disappearance of the infundibular pressure gradient, and right ventricular systolic pressure was 68 mm Hg. The pulmonary artery pressure tracing had a normal configuration. The effective valve area was 1.0 cm^2 (assuming no regurgitation). Right ventricular cinean-

giography showed no infundibular obstruction, and the pulmonic valve orifice increased. No evidence for pulmonic regurgitation was present.

Comments

The potential for right to left shunting through a catheter patent foramen ovale probably helped avoid the profound systolic hypotension and bradycardia during balloon obstruction of the valve orifice, described in the child recently reported.[1] Immediately after relief of valvular obstruction, an infundibular pressure gradient developed in our patient. This is probably analogous to infundibular obstruction often described after surgical valvulotomy for pulmonary stenosis, which generally regresses.[2,3] In our patient infundibular obstruction regressed 10 days after balloon valvuloplasty, and no additional problems were identified.

Acknowledgment: We are indebted to Josh Tolkoff (Meditech) for excellent technical help and fabrication of the catheter, to Robert I. White, MD, for valuable suggestions, to Tom Sollaway, and to the Cardiac Fellows of the University of Florida, Gainesville, Florida.

EFFECTS OF ATRIAL EXTRASTIMULATION AND RAPID PACING ON ATRIAL FLUTTER CYCLE

The excellent report of Inoue et al[1] prompts comments on the mechanism of atrial flutter (AF) in humans. Studying the effects of programmed atrial stimulation on common AF cycle in man, we observed that the poststimulation cycle, recorded at stimulation point, was equal to the basic AF cycle in some patients,[2,3] suggesting that reentry is its electrogenetic mechanism.

Recently we studied 13 patients[4] during episodes of spontaneous common AF with simultaneous multiple atrial endocardial recordings and atrial programmed stimulation. All patients had 1 catheter positioned in the low paraseptal atrium and another in the high right atrium. The 2 sites were named point 1 and point 2, respectively. In all patients low paraseptal atrial activation (point 1) preceded high right atrial activation (point 2), as already documented.[5,6] By programmed single high right atrial (point 2) stimulation, the following were observed: (a) persistence of AF but with early reset of the cycle; (b) however premature the stimulus was, it never modified the simultaneous atrial activation time at point 1; (c) the pattern of atrial activation in the poststimulation atrial complex remained unchanged; (d) the length of the poststimulation atrial cycle recorded at point 1 (that is, a point reached before the stimulation point by the spreading AF wavefront) was always shorter than both the basic AF cycle length and the poststimulation cycle length recorded at point 2. The diagram in Figure 1 represents 1 of these patients.

The existence of a reentry circuit to which the extrastimulus has access before the head of the circus moving wave explains the fact that high atrium-delivered premature stimuli are followed by a poststimulation low atrial recorded cycle length always less than basic AF cycle length, with the following AF activation pattern remaining unchanged.

These results agree with those of Inoue et al,[1] although obtained with different techniques. Thus, we agree with them that there is good evidence of a reentry as electrogenetic mechanism of spontaneous common AF in humans.

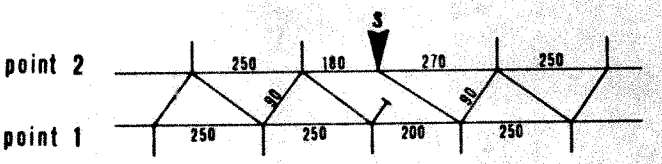

FIGURE 1. Diagram representing 1 of the 13 patients studied.

REPLY: The observations reported by Disertori and Furlanello are identical to those shown in canine atrial flutter (AF).[1] We agree that their observations support the reentry with an excitable gap as the mechanism for human AF.

Some points in their letter deserve comment. First, the phenomenon of the poststimulation cycle being equal to the basic AF cycle does not always support a reentry. As observed by Breithardt et al,[2] if conduction time between the pacing site and the automaticity focus is negligible, the poststimulation cycle might be identical to the basic cycle length. Second, the term *poststimulation cycle* is not appropriate. As shown in the Figure 1, the curtailed cycle on the electrogram of point 1 is a stimulus-encompassing one. Third, in patients with a circus movement turning in the opposite direction, extrastimulation from point 2 may produce a different response, since several factors such as spatial relation between the stimulation site and the recording site,[1] refractory period, and conduction time may modify the effect of extrastimulation.

ATYPICAL D-TRANSPOSITION OF THE GREAT ARTERIES

We have read with interest the case reported by Marin-Garcia and Edwards[1] as "atypical d-transposition with anterior pulmonary trunk." The authors emphasize the importance of their case to the continuing debate concerning the nomenclature of hearts that, in terms of their ventriculoarterial connections, have ventriculoarterial discordance. It seems to us that their own report is most misleading in this respect when they use the term "d-transposition" to describe generally hearts with atrioventricular concordance and ventriculoarterial discordance, a combination to our minds best described as complete transposition. Indeed, at places in their report, Marin-Garcia and Edwards give us the impression that they consider d-transposition synonymous with complete transposition. But this becomes confusing when they state, "In the registry of Cardiovascular Pathology of United Hospitals–Miller Division there are 234 specimens of d-transposition." Does this mean that there are 234 specimens with ventriculoarterial discordance in which the aorta is right-sided? If so, does this number include examples of corrected transposition

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

with situs inversus, in which the aorta is usually d-transposed and, if so, are these justifiably included? Alternatively, does the statement mean that there are 234 specimens with complete transposition? If the latter, does this include examples in which the aorta is directly anterior or left-sided? Perhaps Marin-Garcia and Edwards would describe these cases as "atypical d-transposition with anterior or left-sided aorta"! We submit that "d-transposition" is a most inappropriate synonym for complete transposition if this is in fact intended. This is because it describes what is in essence a "connections malformation" in terms of arterial interrelations. The root of the problems of terminology of transposition has been the failure to distinguish connections from relations.[2]

We also question the interpretation of the morphologic findings, recognizing that this is difficult and indeed, even presumptuous, when we can see only limited photographs. Nonetheless, on the basis of the published illustrations, we suggest that an alternative interpretation is that the pulmonary trunk overrode the anterior ventricular septum, being mostly connected to the right ventricle, and that a more appropriate diagnosis would be double outlet right ventricle. This raises the equally contentious topic of the differentiation of double outlet right ventricle and ventriculoarterial discordance when there is overriding of the pulmonary valve. A significant point in this differentiation is the position of the anterior descending coronary artery. As far as we can judge from Figure 3a, this artery is to the *left* of the pulmonary trunk, suggesting to us that the pulmonary trunk is connected in its greater part to the right ventricle.

Certainly Figure 2 is consistent with the diagnosis of double outlet right ventricle, and Figure 1 does not exclude it since the anterior septum is not profiled. The problem of this type of double outlet right ventricle with sequestration of part of the right ventricle to the left ventricle was recently discussed by Bietzke et al,[3] and their Figure 3 is very similar to Figure 3 of Marin-Garcia and Edwards.[1] The case of Marin-Garcia and Edwards[1] does, of course, have an additional subaortic ventricular septal defect and a subpulmonary infundibulum ("conus").

There is no doubt that the case described by Marin-Garcia and Edwards[1] is closely related to the anomaly of "posterior transposition," this being emphasized by the subaortic defect with mitral-aortic continuity through its roof. However, all previously reported cases of posterior transposition have not had subpulmonary ventricular septal defects and have not had overriding pulmonary valves. The presence of these lesions in this case[1] is further evidence of the "spectrum" of anomalies that exists between double outlet right ventricle and ventriculoarterial discordance.[4] But we submit that the impact of this particular case to the important and ongoing debate concerning nomenclature is blurred by the failure to describe clearly the ventriculoarterial connection and to distinguish it from arterial interrelations.

4. **Goor DA, Edwards JE.** The spectrum of transposition of the great arteries, with special reference to developmental anatomy of the conus. Circulation 1973;48:406–415.

REPLY: We used d-transposition and complete transposition synonymously, stating in the introduction of our manuscript that "the hallmark of d- or complete transposition of the great arteries is connection of the anteriorly lying aorta with the right ventricle, while the posteriorly lying pulmonary trunk arises from the left ventricle." This definition we believe is simple and descriptive. As we stated, in the Registry of Cardiovascular Pathology of United Hospitals there are 234 specimens of d- or complete transposition, and this series does not include cases of corrected transposition.

Based on our experience and others, our case is not an example of double outlet right ventricle. Clinically, it was considered in the differential diagnosis but at necropsy the aortic and pulmonary orifices originated entirely from the right and the left ventricle, respectively. Indeed, there was a second, small ventricular septal defect located below the subpulmonary conus. Quero Jimenez and Perez Martinez[1] reported a similar case (Case 1) where the anterior portion of a large ventricular septal defect was located below the subpulmonary conus. Moreover, Case 3 of Wilkinson and associates[2] exhibited a small blind-ended sinus below the pulmonary valve. It is possible that the sinus represented a patent, subpulmonary ventricular septal defect at some point pre- or postnatally.

In our case the anterior descending artery arose from the left coronary artery, and its course was anterior and to the right of the pulmonary trunk, a feature that cannot be clearly outlined from the published photographs. In our opinion, our case is similar to those originally reported by Van Praagh and associates[3] and the term atypical d- or complete transposition was coined to describe an unusual situation in simple terms that may be helpful to clinicians and surgeons as well.

PREDICTING CARDIAC MORBIDITY

In their article on predicting cardiac morbidity in patients who have undergone coronary angiography, Dimsdale et al[1] use the statistical technique of stepwise discriminant analysis to select the variables which are most important in separating those patients who experience a cardiac event from those who don't. They indicate that the variables selected are highly significant ($p < 0.00005$ for all patients, $p < 0.0001$ when surgical patients are excluded), and report that the use of these variables in a discriminant function results in a high percentage of patients whose fate is correctly predicted (78% for all patients, 83% when surgical patients are excluded). The use and interpretation of this statistical technique in this situation presents some difficulties.

First, the technique used is based on the assumption that the variables in the analysis follow a multivariate normal distribution. Since most of the variables are dichotomous or categorical in nature, the assumption that they are continuous and from a multivariate normal distribution is far from being met. There are other discriminant analysis models which can be used for categorical data, such as the multivariate logistic model,[2] which are designed to overcome these problems. In practice, however, analyses utilizing logistic discrimination often result in variable selections that are similar, if not identical, to that obtained by the use of ordinary discriminant analysis with discrete variables. For that reason, it is quite

possible that a logistic analysis might identify the same variables as being important.

The interpretation of the results in the article is a bit more troublesome. The emphasis on the small p values and high percentage of correct classification imply that the use of these variables in a prediction equation provides a very accurate method of identifying individual patients who will suffer a cardiac event. In fact, the small p values indicate that the patients who experienced cardiac events have mean values for the variables selected in the analysis which are significantly different (in a statistical sense) from the mean values for patients who did not suffer cardiac events, utilizing a multivariate test. It does not say what the magnitude of those differences are, or if such differences would be very useful in identifying patients prone to suffer a cardiac event. The use of the percentage of patients correctly classified is an attempt at an evaluation of how useful the variables are in identifying patients at risk for future events, but the results quoted suggest that the information learned from the analysis is minimal, if it is interpretable at all. For example, in the analysis including all patients given in Table III, it is indicated that 78% of the patients were correctly classified. However, from Table II, one can see that 75% of the patients did not experience a "morbid event," since an emergency room visit was not counted as such an event. Thus, one could correctly classify 75% of the patients, ignoring all the data, by merely predicting that no one would experience any cardiac events. The use of several variables in a complicated statistical equation results in correctly classifying an additional 3% of the patients, not an impressive result. One could better interpret the results if the sensitivity and specificity of the predictions were also given, to see if the predictions were more accurate among those who did suffer events than in those who did not, but that information is not retrievable from the data published.

Timothy A. DeRouen, PhD,
Seattle, Washington

1. **Dimsdale JE, Gilbert J, Hutter AM, Hackett TP, Block P.** Predicting cardiac morbidity based on risk factors and coronary angiographic findings. Am J Cardiol 1981;47:73–76.
2. **Anderson JA.** Logistic discrimination with medical applications. In: Cacoullos T, ed. Discriminant Analysis and Applications. London: Academic Press, 1973:1–15.

REPLY: DeRouen raises some helpful points regarding the interpretation of our approach for predicting subsequent cardiac morbidity. Our article stresses 2 points: (1) that many variables thought related to the clinical course of heart patients were in fact not found related to subsequent cardiac morbidity, (2) that with discriminate analysis, we were able to derive a weighting of those variables found most helpful in predicting subsquent morbidity. Of the many variables studied, these variables (angina, history of myocardial infarction, family history of heart disease, fatigue, and type A personality) were found to contribute the most information in prognosticating subsequent morbidity.

That this approach is statistically useful in discriminating subsequent morbidity is demonstrated by the high levels of significance of the discriminate analysis (for example, $p < 0.00005$ for all patients). DeRouen asks us to expand on aspects of this work that pertain to its clinical utility. We included as a rough measure of clinical utility the total predictive accuracy for our analysis of all followed subjects (n = 189, total accuracy = 78%) and for subjects who had no surgical intervention (n = 111, total accuracy = 83%).

To discuss further the clinical utility of this approach, we need to consider sensitivity (the extent to which patients with subsequent morbidity are correctly classified) and specificity (the extent to which patients who did not develop morbidity are correctly classified).[1] These concepts refer roughly to the ability of our analysis to accurately "rule in" or "rule out" subsequent morbidity.

For the total sample of 189 patients, the sensitivity was 37% and the specificity 93%. For the medically treated sample, these figures were 48 and 93%, respectively. Thus, our approach would appear useful in ruling out patients for subsequent morbidity but of less use in "ruling in" patients for subsequent morbidity. By adjusting the discriminate function cut point, one could increase sensitivity at the expense of decreased specificity or vice versa. This particular cut point was chosen so that the total predictive accuracy would be maximized.

DeRouen asks in essence, "What's so good about 78% predictive accuracy if I can achieve 75% predictive accuracy merely by predicting that no one will develop morbidity?" The consequence of such a decision-making strategy would be 0% sensitivity; Dr. DeRouen would misclassify *all* of the patients who subsequently had morbidity.

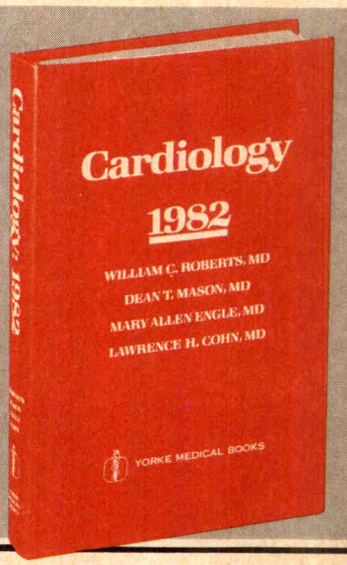
CARDIOLOGY 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

ANGINA
INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.
Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.
INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.
Please see following page for Brief Summary of Prescribing Information.

INDERAL®
(PROPRANOLOL HCl)

THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

The appearance of these tablets is a trademark of Ayerst Laboratories

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors) and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE. In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

– Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

– Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

– Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

– Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-in-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

When technology advances so fast it puts 10-year olds in museums

...you need the Medtronic difference.

Only a decade ago pacemaker technology was led by the Medtronic Chardack™ Model 5910 "programmable" pacemaker. First implanted in the United States in 1972, the unit was programmed invasively, percutaneously introducing a Keith surgical needle into a potentiometer to adjust rate. A cumbersome technique, but the best available then.

However this technology brought a new capability to physicians to restore a more vital life to their patients. *It was technology not for its own sake, but for the patient's sake.* That's part of the Medtronic Difference.

Today we offer you programming options with precise electronic telemetry encapsulated in thin, light titanium housings 72% smaller than units just 10 years ago. These are remarkable programmable pacemakers, each can be noninvasively fine-tuned to alleviate a wide range of cardiac disorders. They can be programmed to meet patient pacing requirements throughout their varying clinical course.

These cost-effective programmable pacing systems, together with Medtronic patient follow-up equipment, make it possible for more patients to resume a full lifestyle. By technologically improving your patient's quality of life with less follow-up required, *the cost of cardiac pacing is steadily decreasing.*

Beyond technology, the Medtronic Difference is having the world's leading pacing company standing behind you. We are ready to assist you in your patient management needs with all our resources.

DECLINING ANNUAL COST OF PACEMAKER PATIENT FOLLOW UP 1965-1980[1].

Medtronic

Discover the Medtronic Difference.

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

for many post-MI patients...

Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after abrupt discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

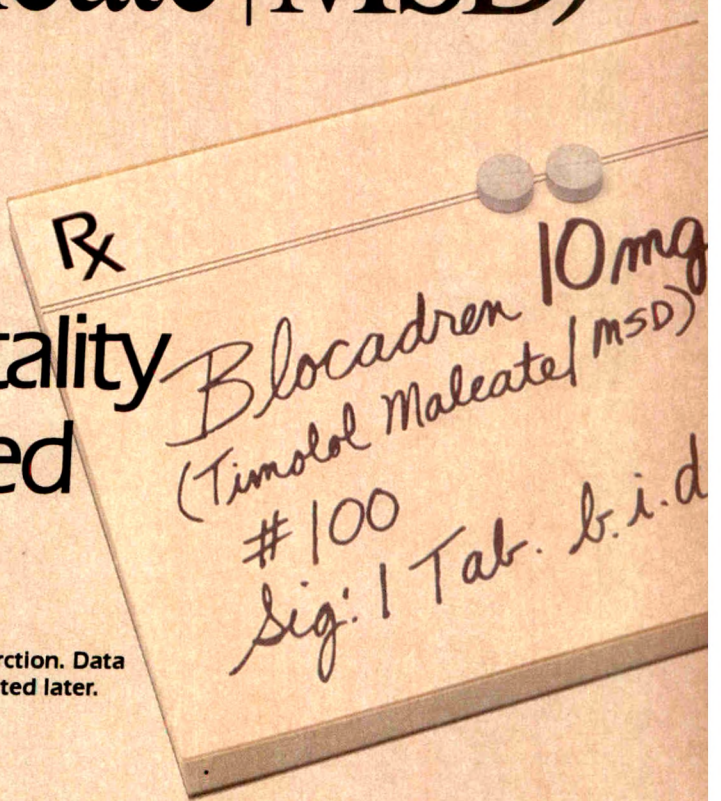
Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients

Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.



disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n = 176) %	Placebo (n = 168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction*		Withdrawal†	
	Timolol (n = 945) %	Placebo (n = 939) %	Timolol (n = 945) %	Placebo (n = 93 %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

*When an adverse reaction recurred in a patient, it i listed only once.

†Only principal reason for withdrawal in each patient i listed.

These adverse reactions can also occur in patient treated for hypertension.

The following additional adverse effects have bee reported in clinical experience with the drug: *Body as Whole*: extremity pain, decreased exercise tolerance weight loss; *Cardiovascular*: cardiac failure, cerebra vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: in addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS) *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

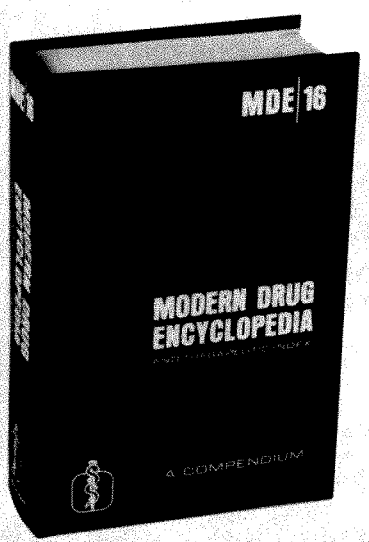
--w th--r--" .. ".. i se is your drug reference?



If it's not the new 16th edition of MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Editor
Gertrude Dittus Gonzales, R.Ph., B.S., Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a–z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension
- designed with a "strong focus" layout, easy-to-reac type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a–z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to reac information on prescription drugs.

Designed with the patient in mind.

People move, bend, stretch, perspire.
When we designed Nitro-Dur™ (nitroglycerin) Transdermal Infusion System, we designed it with features to accommodate these human factors. Because of the size of Nitro-Dur it has features that other nitroglycerin systems don't have.

It's big because it's the only one with a wide adhesive strip.
If angina patients were supine for 24 hours, adhesion would be a minor concern. But people move, bend, stretch, and turn while awake and asleep. A system has to stay put throughout all these movements.

In developing Nitro-Dur, we tested dozens of tapes before we settled on a microporous tape known for its excellent adhesion, one that doesn't leave the skin macerated and is relatively painless on removal.

The Nitro-Dur adhesive strip is wider than that on any other system. Wide enough to stay put during a 24-hour day of walking, showering, bending, standing or sleeping. Wide enough to prevent leaking or falling off.

It's big because it's the only one with an absorbent pad.
Because perspiration could affect adhesion, we added an absorbent pad behind the matrix. Nitro-Dur is the only system with this feature.

Surface area determines the dose.
The stratum corneum regulates the absorption of cutaneously applied nitroglycerin. Therefore, as the surface area of application is increased the dose of nitroglycerin also increases. To insure a fixed surface area, we offer a solid—a gel polymer matrix that contains the active drug.

The only transdermal to offer you greater dosage flexibility.
Nitro-Dur has four dosage strengths—5, 10, 15 and 20 cm^2. Other systems limit your options to two strengths.

The only place it's smaller—the cost to your patients.
Your patients can save up to $75 a year using Nitro-Dur rather than competitive products. Considering that they may be taking the product for years, that's a very important advantage.[1]

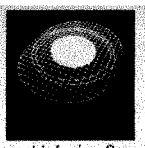
The human factor made us big. You made us the largest-selling transdermal nitroglycerin system.

The most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System



DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

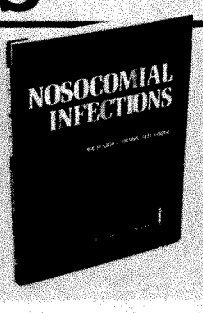
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal*. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

SUBJECT INDEX: VOLUME 50

Action potential
Prolongation of the human cardiac monophasic action potential by sotalol, 1082
Adolescence
Changes in R wave amplitude during aerobic exercise stress testing in hypertensive adolescents, 152
Ajmaline
Use of procainamide in patients with the Wolff-Parkinson-White syndrome to disclose a short refractory period of the accessory pathway, 1087
Ambulatory monitoring
Prognostic implications of ventricular arrhythmias during 24 hour ambulatory monitoring in patients undergoing cardiac catheterization for coronary artery disease, 23
Amiodarone
Amiodarone for control of sustained ventricular tachyarrhythmia: clinical and electrophysiologic effects in 51 patients, 1066
Aneurysms
Cardiac and coronary arterial involvement in infants and children from New England with mucocutaneous lymph node syndrome (Kawasaki disease). Angiocardiographic-echocardiographic correlations, 136
Detection of left ventricular aneurysm on two dimensional echocardiography, 191
Echocardiographic-cineangiographic correlation in detecting left ventricular aneurysm: a prospective study of 422 patients, 337
Pathogenesis of left ventricular aneurysms: an experimental study in the rat model, 83
Prognostic significance of angiographically documented left ventricular aneurysm from the Coronary Artery Surgery Study (CASS), 157
Angina
Postmyocardial infarction angina and coronary spasm, 197
Angina pectoris
Calcium channel blockade as primary therapy for stable angina pectoris. A double-blind placebo-controlled comparison of verapamil and propranolol, 1158
Clinical relevance of verapamil plasma levels in stable angina pectoris, 1180
Comparative effects of abrupt withdrawal of propranolol and verapamil in angina pectoris, 1191
Comparison of oral propranolol and verapamil for combined systemic hypertension and angina pectoris. A placebo-controlled double-blind randomized crossover trial, 1164
Effect of intraaortic balloon counterpulsation on regional myocardial blood flow and oxygen consumption in the presence of coronary artery stenosis: observations in an awake animal model, 829
Effect of nifedipine on exercise-induced left ventricular dysfunction and myocardial hypoperfusion in stable angina, 689
Hemodynamic and clinical effects of combined verapamil and propranolol therapy in angina pectoris, 903
Long-term effectiveness of verapamil in stable and unstable angina pectoris. One-year follow-up of patients treated in placebo-controlled double-blind randomized clinical trials, 1185
Long-term follow-up of verapamil and nitrate treatment for coronary artery spasm, 711
Medical versus surgical treatment of unstable angina, 663
Perioperative coronary arterial spasm: long-term follow-up, 444
Pharmacologic and hemodynamic mechanisms underlying the antianginal actions of verapamil, 886
Randomized double-blind comparison of verapamil and nifedipine in chronic stable angina, 696
Sudden death in Prinzmetal's angina with coronary spasm documented by angiography. Analysis of three necropsy patients, 203
The early pathophysiologic understanding of angina pectoris, 1433
Variability of response to beta receptor blockade for angina pectoris in clinical trials: a study of pindolol, 722
Verapamil therapy for Prinzmetal's variant angina: comparison with placebo and nifedipine, 913
Verapamil therapy for stable and unstable angina pectoris: calcium channel antagonists in perspective, 881
Verapamil therapy for stable exertional angina pectoris, 1153
Verapamil therapy for unstable angina pectoris: review of double-blind placebo-controlled randomized clinical trials, 919
Verapamil versus propranolol for angina at rest, 923
Angiocardiography
Cardiac and coronary arterial involvement in infants and children from New England with mucocutaneous lymph node syndrome (Kawasaki disease). Angiocardiographic-echocardiographic correlations, 136
Compression of the superior vena cava and right atrium in cardiac tamponade, 1287
Detection of left ventricular aneurysm on two dimensional echocardiography, 191
Effects of angiographic contrast medium on isolated canine coronary arteries, 869
Gold-195m, a new generator-produced short-lived radionuclide for sequential assessment of ventricular performance by first pass radionuclide angiocardiography, 89
Improved radiation protection for physicians performing cardiac catheterization, 1283
Myocardial metabolic alterations after contrast angiography, 239
Noninvasive assessment of myocardial contractility in asymptomatic patients with severe aortic regurgitation and normal left ventricular ejection fraction at rest, 45
Prognostic significance of angiographically documented left ventricular aneurysm from the Coronary Artery Surgery Study (CASS 157
Prospective evaluation of radionuclide angiocardiography for the diagnosis of coronary artery disease, 1212
Angioplasty
Laser coronary angioplasty: experience with 9 cadaver hearts, 1209
Transluminal laser catheter angioplasty, 1206
Angiotensin
Coronary hemodynamic effects of angiotensin inhibition by captopril and teprotide in patients with congestive heart failure, 967
Antiarrhythmic therapy
Antiarrhythmic effect of imipramine hydrochloride in patients with ventricular premature complexes without psychological depression, 172
Electrophysiologic effects of flecainide acetate in patients with sinus nodal dysfunction, 1090
Long-term survival of patients with malignant ventricular arrhythmia treated with antiarrhythmic drugs, 437
Anti-inflammatory agents
Current incidence of postmyocardial infarction (Dressler's) syndrome, 1269
Aortic arch
Two dimensional echocardiography and intravenous digital video subtraction angiography for diagnosis and evaluation of double aortic arch, 342
Two-dimensional echocardiographic features of interruption of the aortic arch, 1385
Aortic coarctation
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560
Aortic regurgitation
Detection of mild aortic regurgitation by range-gated pulsed Doppler echocardiography, 1037
Noninvasive assessment of myocardial contractility in asymptomatic patients with severe aortic regurgitation and normal left ventricular ejection fraction at rest, 45
Timing of operation for chronic aortic regurgitation, 325
Aortic stenosis
Exercise electrocardiogram, blood pressure, and working capacity in young patients with valvular or discrete subvalvular aortic stenosis, 769
Aortic valve
Late results after operations for left ventricular outflow tract obstruction, 569
Timing of operation for chronic aortic regurgitation, 325
Argon
Effects of carbon dioxide, Nd-YAG, and argon laser radiation on atheromatous plaques, 1199
Laser coronary angioplasty: experience with 9 cadaver hearts, 1209
Transluminal laser catheter angioplasty, 1206

Arrhythmias
See also Ventricular arrhythmias
A model of chronic ischemic arrhythmias: the relation between electrically inducible ventricular tachycardia, ventricular fibrillation threshold and myocardial infarct size, 469
Atrial excitability and conduction in patients with interatrial conduction defects, 1331
Electrophysiologic drug testing in patients with malignant ventricular arrhythmias: importance of stimulation at more than 1 ventricular site, 1055
Electrophysiologic residua and sequelae of surgery for congenital heart defects, 588
Inter- and intraatrial dissociation during spontaneous atrial flutter: evidence for a focal origin of the arrhythmia, 756
Long-term survival of patients with malignant ventricular arrhythmia treated with antiarrhythmic drugs, 437
Pharmacokinetics of verapamil: experience with a sustained intravenous infusion regimen, 716
Prolongation of the human cardiac monophasic action potential by sotalol, 1082
Subcostal M-mode echocardiography of the right atrial wall in the diagnosis of cardiac arrhythmias, 1104
Atherosclerosis
Effects of carbon dioxide, Nd-YAG, and argon laser radiation on coronary atheromatous plaques, 1199
Athletes
Significance of abnormal electrocardigrams in highly trained athletes, 985
Atrial fibrillation
Atrial excitability and conduction in patients with interatrial conduction defects, 1331
Onset of atrial fibrillation during antidromic tachycardia: association with sudden cardiac arrest and ventricular fibrillation in a patient with Wolff-Parkinson-White syndrome, 353
Verapamil and digoxin: their respective effects on atrial fibrillation and their interaction, 894
Atrial flutter
Inter- and intraatrial dissociation during spontaneous atrial flutter: evidence for a focal origin of the arrhythmia, 756
Atrial septal defect
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560
Long-term follow-up study after closure of secundum atrial septal defect in children: an echocardiographic study, 143
Partial atrioventricular canal defect in elderly patients (aged 60 years or older), 59
Atrioventricular valves
Crisscrossed atrioventricular valves and prolonged survival, 1436
Atrium, right
Subcostal M-mode echocardiography of the right atrial wall in the diagnosis of cardiac arrhythmias, 1104
Atropine
Mechanism of additive effects of digoxin and quinidine on contractility in isolated cardiac muscle, 483
Autonomic nervous system
Influence of the autonomic nervous system on the Q-T interval in man, 1099

Beta-adrenergic blockade
See also specific agents
Hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients on propranolol, 704
Protective effects on isolated hearts with developing infarction: slow channel blockade by diltiazem versus beta-adrenoceptor antagonism by metoprolol, 857
Variability of response to beta receptor blockade for angina pectoris in clinical trials: a study of pindolol, 722
Verapamil therapy for stable exertional angina pectoris, 1153
Bethanidine sulfate
Antiarrhythmic, antifibrillatory, hemodynamic actions of bethanidine sulfate: an orally effective analog of bretylium for suppression of ventricular tachyarrhythmias, 728
Bethesda Conference Report
Delivery system for emergency cardiac care: the medical plan of action, 370
Opening statement, 365
Task Force I: signs and symptoms, 373
Task Force II: prehospital and early hospital care, 377
Task Force III: diagnostic procedures, 382
Task Force IV: pharmacologic interventions, 393
Task Force V: physical interventions and adjunctive therapy, 409
Blood flow
Comparative effects of nitroglycerin and nifedipine on myocardial blood flow and contraction during flow-limiting coronary stenosis in the dog, 281
Evaluation of pulmonary and systemic blood flow by 2-dimensional Doppler echocardiography using fast Fourier transform spectral analysis, 1394
Impaired collateral blood flow reserve early after nontransmural myocardial infarction in concious dogs, 1133
Relation between regional distribution of thallium-201 and myocardial blood flow in normal, acutely ischemic, and infarcted myocardium, 1141
Blood flow, coronary
Exercise-induced decrease in flow through stenotic coronary arteries in the dog, 1409
Extreme protective action of coronary collateral vessels in complete occlusion of the left main coronary artery, 1441
Blood platelets
Plasma beta-thromboglobulin as a measure of platelet activity. Effect of risk factors and findings in ischemic heart disease and after acute myocardial infarction, 1258
Sulfinpyrazone decreases epinephrine-induced platelet aggregation after myocardial infarction, 938
Books received
Books received, 661
Bretylium
Antiarrhythmic, antifibrillatory, hemodynamic actions of bethanidine sulfate: an orally effective analog of bretylium for suppression of ventricular tachyarrhythmias, 728
Bundle branches
Electrotonic modulation of the T wave and cardiac memory, 213
Electrotonic modulation of the T wave, 361
Phase image characterization of ventricular contraction in left and right bundle branch block, 95
Transient T wave abnormalities in intermittent bundle branch block, 363
Value of the H-Q interval in patients with bundle branch block and the role of prophylactic permanent pacing, 1316

Calcium antagonists
See also specific agents
Effect of nifedipine on exercise-induced left ventricular dysfunction and myocardial hypoperfusion in stable angina, 689
Hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients on propranolol, 704
Inhibition of hypoxic pulmonary vasoconstriction by nifedipine, 864
Protective effects on isolated hearts with developing infarction: slow channel blockade by diltiazem versus beta-adrenoceptor antagonism by metoprolol, 857
Randomized double-blind comparison of verapamil and nifedipine in chronic stable angina, 696
Verapamil therapy for stable and unstable angina pectoris: calcium channel antagonists in perspective, 881
Captopril
Coronary hemodynamic effects of angiotensin inhibition by captopril and teprotide in patients with congestive heart failure, 967
Carcinoid heart disease
Echocardiographic features of carcinoid heart disease, 762
Cardiac arrest
Characteristics of survivors of exertion- and nonexertion-related cardiac arrest: value of subsequent exercise testing, 671
Cardiac catheterization
Anatomic and prognostic implications of an early positive treadmill exercise test, 682
Pediatric cardiac catheterization with same-day discharge, 800
Cardiac output
Evaluation of pulmonary and systemic blood flow by 2-dimensional Doppler echocardiography using fast Fourier transform spectral analysis, 1394
Cardiac surgery
Constrictive pericarditis as a complication of cardiac surgery: recognition of an entity, 742
Cardiac tamponade
Compression of the superior vena cava and right atrium in cardiac tamponade, 1287
Echocardiographic study of right ventricular wall motion in cardiac tamponade, 1018
Cardiomyopathy
Constrictive pericarditis: new aspects, 1014

Hypothesis: is congestive cardiomyopathy caused by a hyperreactive myocardial microcirculation (microvascular spasm)? 1149
Nonobstructive hypertrophic cardiomyopathy: a precise assessment of hemodynamic characteristics and clinical implications, 990

Catheters
Improved radiation protection for physicians performing cardiac catheterization, 1283
Low energy countershock using an intravascular catheter in an acute cardiac care setting, 1124
Transluminal laser catheter angioplasty, 1206

Children
Two-dimensional echocardiographic assessment of right ventricular volumes in children with congenital heart disease, 1368

Cineangiography
Echocardiographic-cineangiographic correlation in detecting left ventricular aneurysm: a prospective study of 422 patients, 337
Limitations of comparing left ventricular volumes by two dimensional echocardiography, myocardial markers and cineangiography, 512

Computed tomography
Measurement of infarct size using single photon emission computed tomography and technetium-99m pyrophosphate: a description of the method and comparison with patient prognosis, 503

Congenital heart defects
See also Pediatric cardiology
Clinical problems of postoperative pulmonary vascular disease, 631
Conotruncal malformations: diagnosis in infancy using subxiphoid 2 dimensional echocardiography, 1361
Electrophysiologic residua and sequelae of surgery for congenital heart defects, 588
Epilogue: the pathologist, 652
Exercise electrocardiogram, blood pressure, and working capacity in young patients with valvular or discrete subvalvular aortic stenosis, 769
Late results after operations for left ventricular outflow tract obstruction, 569
Long-term effects of prosthetic materials, 621
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560
Mechanism of acquired right ventricular outflow tract obstruction in patients with ventricular septal defect: an angiocardiographic study, 776
Myocardial injury in infants with congenital heart disease: evaluation by creatine kinase MB isoenzyme analysis, 129
Pregnancy and its outcome in women with and without surgical treatment of congenital heart disease, 641
Sequelae of atriotomy and ventriculotomy on the endocardium, conduction system and coronary arteries, 580
Surgical repair of congenitally corrected transposition of the great arteries: results and follow-up, 781
Two-dimensional echocardiographic assessment of dextrocardia: a segmental approach, 1351
Two-dimensional echocardiographic assessment of right ventricular volumes in children with congenital heart disease, 1368
Two-dimensional echocardiographic evaluation of persistent truncus arteriosus, 1376
Two-dimensional echocardiographic prospective diagnosis of common truncus arteriosus in infants, 1380
Ventricular performance in adults after operation for congenital heart disease, 612
World survey of the common cardiac malformations: developmental error or genetic variant? 544

Congestive heart failure
Assessment of vasodilator therapy in patients with severe congestive heart failure: limitations of measurements of left ventricular ejection fraction and volumes, 954
Coronary hemodynamic effects of angiotensin inhibition by captopril and teprotide in patients with congestive heart failure, 967
Hypothesis: is congestive cardiomyopathy caused by a hyperreactive myocardial microcirculation (microvascular spasm)? 1149
Prostacyclin therapy in patients with congestive heart failure, 320

Contractile reserve
Inotropic contractile reserve: a useful predictor of increased 5 year survival and improved postoperative left ventricular function in patients with coronary artery disease and reduced ejection fraction, 39

Contrast media
Myocardial metabolic alterations after contrast angiography, 239

Coronary arteries
Effects of angiographic contrast medium on isolated canine coronary arteries, 869
Embolus to the left main coronary artery, 658
Exercise-induced decrease in flow through stenotic coronary arteries in the dog, 1409
Hemodynamics of multiple versus single 50 percent coronary arterial stenoses, 276
Quantitative comparison of extent of coronary narrowing and size of healed myocardial infarct in 33 necropsy patients with clinically recognized and in 28 with clinically unrecognized ("silent") previous acute myocardial infarction, 677
Sequelae of atriotomy and ventriculotomy on the endocardium, conduction system and coronary arteries, 580

Coronary artery disease
Anatomic and prognostic implications of an early positive treadmill exercise test, 682
Application of body surface mapping to exercise testing: S-T_{80} isoarea maps in patients with coronary artery disease, 1109
Assessment of the use of the age- and sex- specific United States population as a control group for analysis of survival in coronary artery disease, 1279
Cardiac effects of prolonged and intense exercise training in patients with coronary artery disease, 246
Cold pressor thallium-201 myocardial scintigraphy in the diagnosis of coronary artery disease, 1253
Coronary collateral vessels: spectrum o physiologic capabilities with respect t providing rest and stress myocardial perfusion, maintenance of left ventricular function and protection against infarction, 230
Effect of nifedipine on exercise-induced left ventricular dysfunction and myocardial hypoperfusion in stable angina, 689
Effects of carbon dioxide, Nd-YAG, and argon laser radiation on coronary atheromatous plaques, 1199
Enhanced transcardiac l-norepinephrine response during cold pressor test in obstructive coronary artery disease, 1223
Familial aggregation of coronary heart disease and its relation to known genetic risk factors, 945
Impaired collateral blood flow reserve early after nontransmural myocardial infarction in concious dogs, 1133
Importance of coronary risk factors in th presence or absence of myocardial ischemia, 1248
Increased physical activity: a protective factor against heart attacks in Puerto Rico, 749
Inotropic contractile reserve: a useful predictor of increased 5 year survival and improved postoperative left ventricular function in patients with coronary artery disease and reduced ejection fraction, 39
Noninvasive detection of multivessel disease after myocardial infarction by exercise radionuclide ventriculograph 1242
Perioperative coronary arterial spasm: long-term follow-up, 444
Plasma beta-thromboglobulin as a measure of platelet activity. Effect of risk factors and findings in ischemic heart disease and after acute myocardial infarction, 1258
Prospective evaluation of radionuclide angiocardiography for the diagnosis c coronary artery disease, 1212
Role of electrophysiologic testing in managing patients who have ventricular tachycardia unrelated to coronary artery disease, 165
The QT > QS_2 syndrome: a new mortal risk indicator in coronary artery disease, 1229

Coronary artery, left main
Extreme protective action of coronary collateral vessels in complete occlusion of the left main coronary artery, 1441

Coronary artery, right
Serial right ventricular thallium-201 imaging after exercise: relation to anatomy of the right coronary artery, 1217

Coronary spasm
Long-term follow-up of verapamil and nitrate treatment for coronary artery spasm, 711
Perioperative coronary arterial spasm: long-term follow-up, 444

Postmyocardial infarction angina and coronary spasm, 197
Sudden death in Prinzmetal's angina with coronary spasm documented by angiography. Analysis of three necropsy patients, 203
Counterpulsation, intraaortic balloon
Effect of intraaortic balloon counterpulsation on regional myocardial blood flow and oxygen consumption in the presence of coronary artery stenosis: observations in an awake animal model, 829
Creatine kinase
Electrophysiologic study for ventricular arrhythmia: effect on total and myocardial-specific creatine kinase activity, 1061
Myocardial injury in infants with congenital heart disease: evaluation by creatine kinase MB isoenzyme analysis, 129

Dermatomyositis
The heart and cardiac conduction system in polymyositis-dermatomyositis: a clinicopathologic study of 16 autopsied patients, 998
Dextrocardia
Two-dimensional echocardiographic assessment of dextrocardia: a segmental approach, 1351
Digoxin
Mechanism of additive effects of digoxin and quinidine on contractility in isolated cardiac muscle, 483
Verapamil and digoxin: their respective effects on atrial fibrillation and their interaction, 894
Diltiazem
Protective effects on isolated hearts with developing infarction: slow channel blockade by diltiazem versus beta-adrenoceptor antagonism by metoprolol, 857
Doppler ultrasound
Detection of ischemic myocardium in vivo through the chest wall by quantitative ultrasonic tissue characterization, 838
Detection of mild aortic regurgitation by range-gated pulsed Doppler echocardiography, 1037
Evaluation of pulmonary and systemic blood flow by 2-dimensional Doppler echocardiography using fast Fourier transform spectral analysis, 1394

Echocardiography
Cardiac and coronary arterial involvement in infants and children from New England with mucocutaneous lymph node syndrome (Kawasaki disease). Angiocardiographic-echocardiographic correlations, 136
Cardiac effects of prolonged and intense exercise training in patients with coronary artery disease, 246
Compression of the superior vena cava and right atrium in cardiac tamponade, 1287
Conotruncal malformations: diagnosis in infancy using subxiphoid 2 dimensional echocardiography, 1361
Detection of left ventricular aneurysm on two dimensional echocardiography, 191
Detection of mild aortic regurgitation by range-gated pulsed Doppler echocardiography, 1037
Early hypertension and cardiac work, 149
Echocardiographic-cineangiographic correlation in detecting left ventricular aneurysm: a prospective study of 422 patients, 337
Echocardiographic features of carcinoid heart disease, 762
Echocardiographic study of right ventricular wall motion in cardiac tamponade, 1018
Effect of beam directional alterations on left ventricular shortening fraction, 1120
Effects of amyl nitrite on left ventricular relaxation in patients with borderline hypertension, 979
Evaluation of pulmonary and systemic blood flow by 2-dimensional Doppler echocardiography using fast Fourier transform spectral analysis, 1394
Intraoperative 2-dimensional echocardiography: ejection of microbubbles from the left ventricle after cardiac surgery, 1130
Limitations of comparing left ventricular volumes by two dimensional echocardiography, myocardial markers and cineangiography, 512
Long-term follow-up study after closure of secundum atrial septal defect in children: an echocardiographic study, 143
Quantitation and significance of horizontal cardiac motion in M mode and two dimensional echocardiography, 520
Sensitivity and specificity of M mode echocardiographic signs of mitral valve prolapse, 185
Subcostal M-mode echocardiography of the right atrial wall in the diagnosis of cardiac arrhythmias, 1104
Task Force III: diagnostic procedures, 382
Two-dimensional echocardiographic evaluation of persistent truncus arteriosus, 1376
Two-dimensional echocardiographic features of interruption of the aortic arch, 1385
Two-dimensional echocardiographic findings in cardiac trauma, 1022
Two-dimensional echocardiographic identification of pulmonary artery branch stenosis, 814
Two-dimensional echocardiographic prospective diagnosis of common truncus arteriosus in infants, 1380
Two dimensional echocardiography and intravenous digital video subtraction angiography for diagnosis and evaluation of double aortic arch, 342
Ejection fraction
Physiologic correlates of right ventricular ejection fraction in chronic obstructive pulmonary disease: a combined radionuclide and hemodynamic study, 255
Scintigraphic prediction of pulmonary arterial systolic pressure by regional right ventricular ejection fraction during the second half of systole, 1114
Elderly patients
Partial atrioventricular canal defect in elderly patients (aged 60 years or older), 59
Electrical stimulation
Response to programmed ventricular stimulation: sensitivity, specificity and relation to heart disease, 452
Electrocardiography
Antiarrhythmic effect of imipramine hydrochloride in patients with ventricular premature complexes without psychological depression, 172
Application of body surface mapping to exercise testing: S-T_{80} isoarea maps in patients with coronary artery disease, 1109
Changes in R wave amplitude during aerobic exercise stress testing in hypertensive adolescents, 152
Clinical and electrophysiologic findings in patients with repetitive monomorphic ventricular tachycardia and otherwise normal electrocardiogram, 459
Clinical implications of anterior S-T segment depression in patients with acute inferior myocardial infarction, 428
Detection of acute right ventricular infarction by right precordial electrocardiography, 421
Evaluation of normal variations in S-T segment patterns by body surface isopotential mapping: S-T segment elevation in absence of heart disease, 122
Exercise electrocardiogram, blood pressure, and working capacity in young patients with valvular or discrete subvalvular aortic stenosis, 769
Significance of abnormal electrocardigrams in highly trained athletes, 985
Task Force III: diagnostic procedures, 382
Ventricular activation during ventricular endocardial pacing. I. Electrocardiographic patterns related to the site of pacing, 1
Electrophysiologic studies
Amiodarone for control of sustained ventricular tachyarrhythmia: clinical and electrophysiologic effects in 51 patients, 1066
Atrial excitability and conduction in patients with interatrial conduction defects, 1331
Clinical and electrophysiologic findings in patients with repetitive monomorphic ventricular tachycardia and otherwise normal electrocardiogram, 459
Effects of verapamil on the electrophysiologic properties of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, 1323
Electrophysiologic drug testing in patients with malignant ventricular arrhythmias: importance of stimulation at more than 1 ventricular site, 1055
Electrophysiologic effects of flecainide acetate in patients with sinus nodal dysfunction, 1090
Electrophysiologic residua and sequelae of surgery for congenital heart defects, 588
Electrophysiologic study for ventricular arrhythmia: effect on total and myocardial-specific creatine kinase activity, 1061
Electrophysiologic testing in the evaluation of patients with syncope of undetermined origin, 1309

Electrotonic modulation of the T wave and cardiac memory, 213
Epicardial activation of the human ventricle: effects of left ventricular hypertrophy, 1095
Local effects of electrical and mechanical stimulation on the recovery properties of the canine ventricle, 263
Prediction of sudden death by electrophysiologic studies in high risk patients surviving acute myocardial infarction, 223
Prolongation of the human cardiac monophasic action potential by sotalol, 1082
Quintuple pathways participating in three distinct types of atrioventricular reciprocating tachycardia in a patient with Wolff-Parkinson-White syndrome, 347
Role of electrophysiologic testing in managing patients who have ventricular tachycardia unrelated to coronary artery disease, 165
The QT > QS_2 syndrome: a new mortality risk indicator in coronary artery disease, 1229
Value of the H-Q interval in patients with bundle branch block and the role of prophylactic permanent pacing, 1316

Electrophysiologic testing
Response to programmed ventricular stimulation: sensitivity, specificity and relation to heart disease, 452

Embolism
Embolus to the left main coronary artery, 658
Intraoperative 2-dimensional echocardiography: ejection of microbubbles from the left ventricle after cardiac surgery, 1130

Emergency cardiac care
Delivery system for emergency cardiac care: the medical plan of action, 370
Emergency cardiac care—bootstrapping to 2,000 AD, 539
Opening statement, 365

Encainide
Comparison of the effects of placebo and encainide on programmed electrical stimulation and ventricular arrhythmia frequency, 305

Endocardium
Partial atrioventricular canal defect in elderly patients (aged 60 years or older), 59
Sequelae of atriotomy and ventriculotomy on the endocardium, conduction system and coronary arteries, 580
Ventricular activation during ventricular endocardial pacing. I. Electrocardiographic patterns related to the site of pacing, 1
Ventricular activation during ventricular endocardial pacing. II. Role of pace-mapping to localize origin of ventricular tachycardia, 11

Epicardium
Effect of changes in perfusion pressure on the position of the electrophysiologic border zone in acute regional ischemia in isolated perfused dog and pig hearts, 74

Epidemiologic studies
Assessment of the use of the age- and sex- specific United States population as a control group for analysis of survival in coronary artery disease, 1279
Increased physical activity: a protective factor against heart attacks in Puerto Rico, 749

Epinephrine
Sulfinpyrazone decreases epinephrine-induced platelet aggregation after myocardial infarction, 938

Exercise
Increased physical activity: a protective factor against heart attacks in Puerto Rico, 749

Exercise testing
Accuracy of cardiac output, oxygen uptake, and arteriovenous oxygen difference at rest, during exercise, and after vasodilator therapy in patients with severe, chronic heart failure, 973
Anatomic and prognostic implications of an early positive treadmill exercise test, 682
Application of body surface mapping to exercise testing: S-T_{80} isoarea maps in patients with coronary artery disease, 1109
Cardiac effects of prolonged and intense exercise training in patients with coronary artery disease, 246
Changes in R wave amplitude during aerobic exercise stress testing in hypertensive adolescents, 152
Characteristics of survivors of exertion- and nonexertion-related cardiac arrest: value of subsequent exercise testing, 671
Exercise electrocardiogram, blood pressure, and working capacity in young patients with valvular or discrete subvalvular aortic stenosis, 769
Exercise-induced decrease in flow through stenotic coronary arteries in the dog, 1409
Factors influencing estimated oxygen uptake during exercise testing soon after myocardial infarction, 299
Serial right ventricular thallium-201 imaging after exercise: relation to anatomy of the right coronary artery, 1217

Flecainide acetate
Electrophysiologic effects of flecainide acetate in patients with sinus nodal dysfunction, 1090

Genetics
Familial aggregation of coronary heart disease and its relation to known genetic risk factors, 945

Heart failure
Accuracy of cardiac output, oxygen uptake, and arteriovenous oxygen difference at rest, during exercise, and after vasodilator therapy in patients with severe, chronic heart failure, 973
Effects of acute and chronic minoxidil administration on rest and exercise hemodynamics and clinical status in patients with severe, chronic heart failure, 960

Heart murmurs
Hemodynamic determinants of the frequency and amplitude of a musical murmur produced by a regurgitant mitral bioprosthetic valve, 53

Heart surgery
Prognostic significance of angiographically documented left ventricular aneurysm from the Coronary Artery Surgery Study (CASS), 157

Hemodynamics
Early assessment of hemodynamic status after repair of tetralogy of Fallot: a comparison of 24 hour (intensive care unit) and 1 year postoperative data in 98 patients, 795
Effects of acute and chronic minoxidil administration on rest and exercise hemodynamics and clinical status in patients with severe, chronic heart failure, 960
Hemodynamics of multiple versus single 50 percent coronary arterial stenoses, 276
Large V waves in the pulmonary wedge pressure tracing in the absence of mitral regurgitation, 1044
Nonobstructive hypertrophic cardiomyopathy: a precise assessment of hemodynamic characteristics and clinical implications, 990
Pharmacologic and hemodynamic mechanisms underlying the antianginal actions of verapamil, 886

Hemorrhage, cerebral
Occlusive thromboaortopathy (Takayasu's disease) and pregnancy. Clinical course and management of 33 pregnancies and deliveries, 1293

History of cardiology
Jacob Mendez DaCosta: medical teacher, clinician, and clinical investigator, 1145
The early pathophysiologic understanding of angina pectoris, 1433
Tribute to Paul Wood, 1431

Hypertension
Changes in R wave amplitude during aerobic exercise stress testing in hypertensive adolescents, 152
Comparison of oral propranolol and verapamil for combined systemic hypertension and angina pectoris. A placebo-controlled double-blind randomized crossover trial, 1164
Early hypertension and cardiac work, 149
Effects of amyl nitrite on left ventricular relaxation in patients with borderline hypertension, 979
Effects of hypertension on cardiac performance in rats with myocardial infarction, 488
Inhibition of hypoxic pulmonary vasoconstriction by nifedipine, 864

Hypertrophy
Epicardial activation of the human ventricle: effects of left ventricular hypertrophy, 1095
Hypothesis: is congestive cardiomyopathy caused by a hyperreactive myocardial microcirculation (microvascular spasm)? 1149
Nonobstructive hypertrophic cardiomyopathy: a precise assessment of hemodynamic characteristics and clinical implications, 990

Hypoxia
Inhibition of hypoxic pulmonary vasoconstriction by nifedipine, 864

Ibuprofen
Ibuprofen-mediated infarct size reduction: effects on regional myocardial function in canine myocardial infarction, 849
Infants
Conotruncal malformations: diagnosis in infancy using subxiphoid 2 dimensional echocardiography, 1361
Two-dimensional echocardiographic prospective diagnosis of common truncus arteriosus in infants, 1380
Two-dimensional echocardiographic features of interruption of the aortic arch, 1385
Infection
Immune reactions in tuberculous and chronic constrictive pericarditis. Clinical data and diagnostic significance of antimyocardial antibodies, 1007
Ischemia
Clinical implications of anterior S-T segment depression in patients with acute inferior myocardial infarction, 428
Detection of ischemic myocardium in vivo through the chest wall by quantitative ultrasonic tissue characterization, 838
Digital intravenous ventriculography: analysis and validation of wall thickness changes during ischemia and inotropic stimulation in dogs, 874
Effect of changes in perfusion pressure on the position of the electrophysiologic border zone in acute regional ischemia in isolated perfused dog and pig hearts, 74
Effects of sulfinpyrazone on ventricular vulnerability in the normal and the ischemic heart, 271
Importance of coronary risk factors in the presence or absence of myocardial ischemia, 1248
Increased R-wave amplitude induced by acute myocardial ischemia in the dog: a predictor of malignant ventricular arrhythmias, 844
Intracoronary thrombolysis in acute myocardial infarction: duration of ischemia as a major determinant of late results after recanalization, 933
Plasma beta-thromboglobulin as a measure of platelet activity. Effect of risk factors and findings in ischemic heart disease and after acute myocardial infarction, 1258
Relation between regional distribution of thallium-201 and myocardial blood flow in normal, acutely ischemic, and infarcted myocardium, 1141
Relation between regional myocardial uptake of rubidium-82 and perfusion: absolute reduction of cation uptake in ischemia, 112
Spatial distribution of [^{14}C]-lidocaine and blood flow in transmural and lateral border zones of ischemic canine myocardium, 63
Ventricular fibrillation resulting from ischemia at a site remote from previous myocardial infarction. A conscious canine model of sudden coronary death, 1414
Ventricular performance and biochemical alteration of regional ischemic myocardium after reperfusion in the pig, 821
Isoproterenol
Effect of isoproterenol on the anterograde refractory period of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, 180
Kawasaki disease
Cardiac and coronary arterial involvement in infants and children from New England with mucocutaneous lymph node syndrome (Kawasaki disease). Angiocardiographic-echocardiographic correlations, 136
Lasers
Effects of carbon dioxide, Nd-YAG, and argon laser radiation on coronary atheromatous plaques, 1199
Laser coronary angioplasty: experience with 9 cadaver hearts, 1209
Transluminal laser catheter angioplasty, 1206
Letters to the Editor
Atypical D-transposition of the great arteries, 1443
Cardiolocution and dysrhythmia, 1198
Coronary collateral vessels in cyanotic congenital heart disease, 662
Definition of ventricular tachycardia, 1197
Effects of atrial extrastimulation and rapid pacing on atrial flutter cycle, 1444
Ejection fraction and atrial pacing, 662
Nifedipine therapy for small vessel disease of the heart, 211
Predicting cardiac morbidity, 1444
Proper identification of trademarked products, 929
The morphologic method applied to the problem of "single" right ventricle, 929
Withdrawal of 2 previously published reports, 929
Lidocaine
Regional myocardial lidocaine concentration following continuous intravenous infusion early and late after myocardial infarction, 497
Spatial distribution of [^{14}C]-lidocaine and blood flow in transmural and lateral border zones of ischemic canine myocardium, 63
Mapping
Evaluation of normal variations in S-T segment patterns by body surface isopotential mapping: S-T segment elevation in absence of heart disease, 122
Mapping, body surface
Application of body surface mapping to exercise testing: S-T_{80} isoarea maps in patients with coronary artery disease, 1109
Metoprolol
Protective effects on isolated hearts with developing infarction: slow channel blockade by diltiazem versus beta-adrenoceptor antagonism by metoprolol, 857
Mexiletine
Lack of effectiveness of oral mexiletine in patients with drug-refractory paroxysmal sustained ventricular tachycardia. A study utilizing programmed stimulation, 1075
Minoxidil
Effects of acute and chronic minoxidil administration on rest and exercise hemodynamics and clinical status in patients with severe, chronic heart failure, 960
Mitral regurgitation
Hemodynamic determinants of the frequency and amplitude of a musical murmur produced by a regurgitant mitral bioprosthetic valve, 53
Large V waves in the pulmonary wedge pressure tracing in the absence of mitral regurgitation, 1044
Mitral valve
Sensitivity and specificity of M mode echocardiographic signs of mitral valve prolapse, 185
Myocardial infarction
A model of chronic ischemic arrhythmias: the relation between electrically inducible ventricular tachycardia, ventricular fibrillation threshold and myocardial infarct size, 469
Clinical implications of anterior S-T segment depression in patients with acute inferior myocardial infarction, 428
Current incidence of postmyocardial infarction (Dressler's) syndrome, 1269
Detection of acute right ventricular infarction by right precordial electrocardiography, 421
Effects of hypertension on cardiac performance in rats with myocardial infarction, 488
Factors influencing estimated oxygen uptake during exercise testing soon after myocardial infarction, 299
Familial aggregation of coronary heart disease and its relation to known genetic risk factors, 945
Ibuprofen-mediated infarct size reduction: effects on regional myocardial function in canine myocardial infarction, 849
Impaired collateral blood flow reserve early after nontransmural myocardial infarction in concious dogs, 1133
Intracoronary thrombolysis in acute myocardial infarction: correlations among serum enzyme, scintigraphic and hemodynamic findings, 32
Measurement of infarct size using single photon emission computed tomograph and technetium-99m pyrophosphate: description of the method and comparison with patient prognosis, 5(
Medical versus surgical treatment of unstable angina, 663
Noninvasive detection of multivessel disease after myocardial infarction by exercise radionuclide ventriculography 1242
Pathogenesis of left ventricular aneurysms: an experimental study in the rat model, 83
Perioperative coronary arterial spasm: long-term follow-up, 444
Postmyocardial infarction angina and coronary spasm, 197
Prediction of sudden death by electrophysiologic studies in high risk patients surviving acute myocardial infarction, 223
Protective effects on isolated hearts with developing infarction: slow channel blockade by diltiazem versus beta-adrenoceptor antagonism by metoprolol, 857

Quantitative assessment of infarct size reduction by coronary venous retroperfusion in baboons, 1424
Quantitative comparison of extent of coronary narrowing and size of healed myocardial infarct in 33 necropsy patients with clinically recognized and in 28 with clinically unrecognized ("silent") previous acute myocardial infarction, 677
Regional myocardial lidocaine concentration following continuous intravenous infusion early and late after myocardial infarction, 497
Spontaneous changes in thallium-201 myocardial perfusion imaging after myocardial infarction, 1272
Sulfinpyrazone decreases epinephrine-induced platelet aggregation after myocardial infarction, 938
Transaxial tomography with thallium-201 for detecting remote myocardial infarction. Comparison with planar imaging, 1236
Use of QRS scoring and thallium-201 scintigraphy to assess left ventricular function after myocardial infarction, 1262
Ventricular fibrillation resulting from ischemia at a site remote from previous myocardial infarction. A conscious canine model of sudden coronary death, 1414

Myocardial infarction, acute
Intracoronary thrombolysis in acute myocardial infarction: duration of ischemia as a major determinant of late results after recanalization, 933
Plasma beta-thromboglobulin as a measure of platelet activity. Effect of risk factors and findings in ischemic heart disease and after acute myocardial infarction, 1258

Myocardial perfusion
Coronary collateral vessels: spectrum of physiologic capabilities with respect to providing rest and stress myocardial perfusion, maintenance of left ventricular function and protection against infarction, 230
Relation between regional myocardial uptake of rubidium-82 and perfusion: absolute reduction of cation uptake in ischemia, 112

Myocardium
Detection of ischemic myocardium in vivo through the chest wall by quantitative ultrasonic tissue characterization, 838
Digital intravenous ventriculography: analysis and validation of wall thickness changes during ischemia and inotropic stimulation in dogs, 874
Early hypertension and cardiac work, 149
Effect of intraaortic balloon counterpulsation on regional myocardial blood flow and oxygen consumption in the presence of coronary artery stenosis: observations in an awake animal model, 829
Ibuprofen-mediated infarct size reduction: effects on regional myocardial function in canine myocardial infarction, 849
Increased R-wave amplitude induced by acute myocardial ischemia in the dog: a predictor of malignant ventricular arrhythmias, 844
Myocardial injury in infants with congenital heart disease: evaluation by creatine kinase MB isoenzyme analysis, 129
Myocardial metabolic alterations after contrast angiography, 239
Noninvasive assessment of myocardial contractility in asymptomatic patients with severe aortic regurgitation and normal left ventricular ejection fraction at rest, 45
Relation between regional distribution of thallium-201 and myocardial blood flow in normal, acutely ischemic, and infarcted myocardium, 1141
Spatial distribution of [^{14}C]-lidocaine and blood flow in transmural and lateral border zones of ischemic canine myocardium, 63
The heart and cardiac conduction system in polymyositis-dermatomyositis: a clinicopathologic study of 16 autopsied patients, 998
Ventricular performance and biochemical alteration of regional ischemic myocardium after reperfusion in the pig, 821

Nifedipine
Assessment of left ventricular relaxation in patients with valvular regurgitation, 1028
Comparative effects of nitroglycerin and nifedipine on myocardial blood flow and contraction during flow-limiting coronary stenosis in the dog, 281
Effect of nifedipine on exercise-induced left ventricular dysfunction and myocardial hypoperfusion in stable angina, 689
Hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients on propranolol, 704
Inhibition of hypoxic pulmonary vasoconstriction by nifedipine, 864
Long-term follow-up of verapamil and nitrate treatment for coronary artery spasm, 711
Randomized double-blind comparison of verapamil and nifedipine in chronic stable angina, 696
Rationale for the choice of calcium antagonists in chronic stable angina. An objective double-blind placebo-controlled comparison of nifedipine and verapamil, 1173
Verapamil therapy for Prinzmetal's variant angina: comparison with placebo and nifedipine, 913

Nitroglycerin
Comparative effects of nitroglycerin and nifedipine on myocardial blood flow and contraction during flow-limiting coronary stenosis in the dog, 281
Reversal of regional myocardial depressant effects of propranolol with nitroglycerin, 478

Norepinephrine
Enhanced transcardiac l-norepinephrine response during cold pressor test in obstructive coronary artery disease, 1223

Nuclear medicine
Continuous monitoring of left ventricular performance with the computerized nuclear probe during laryngoscopy and intubation before coronary artery bypass surgery, 735

Oxygen
Accuracy of cardiac output, oxygen uptake, and arteriovenous oxygen difference at rest, during exercise, an after vasodilator therapy in patients with severe, chronic heart failure, 973
Effect of intraaortic balloon counterpulsation on regional myocardial blood flow and oxygen consumption in the presence of coronary artery stenosis: observations in an awake animal model, 829
Factors influencing estimated oxygen uptake during exercise testing soon after myocardial infarction, 299

Pacing, atrial
Influence of the autonomic nervous system on the Q-T interval in man, 1099

Pacing, cardiac
Local effects of electrical and mechanical stimulation on the recove properties of the canine ventricle, 26
The value of the H-Q interval in patients with bundle branch block and the role of prophylactic permanent pacing, 1316

Pacing, endocardial
Ventricular activation during ventricular endocardial pacing. I. Electrocardiographic patterns related the site of pacing, 1
Ventricular activation during ventricular endocardial pacing. II. Role of pace-mapping to localize origin of ventricular tachycardia, 11

Pacing, ventricular
Electrotonic modulation of the T wave and cardiac memory, 213
Termination of ventricular tachycardia. Evaluation of a new pacing method, 1338

Patent ductus arteriosus
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560

Pediatric cardiology
See also Congenital heart defects
Cardiac and coronary arterial involveme in infants and children from New England with mucocutaneous lymph node syndrome (Kawasaki disease). Angiocardiographic-echocardiographi correlations, 136
Compression of intrapulmonary bronchi by abnormally branching pulmonary arteries associated with absent pulmonary valves, 804
Early assessment of hemodynamic statu after repair of tetralogy of Fallot: a comparison of 24 hour (intensive car unit) and 1 year postoperative data in 98 patients, 795
Late results after operations for left ventricular outflow tract obstruction, 569
Long-term follow-up study after closure secundum atrial septal defect in children: an echocardiographic study, 143
Myocardial injury in infants with congenital heart disease: evaluation b creatine kinase MB isoenzyme analysis, 129
Pediatric cardiac catheterization with same-day discharge, 800

Two-dimensional echocardiographic features of interruption of the aortic arch, 1385
Two-dimensional echocardiographic identification of pulmonary artery branch stenosis, 814
Two-dimensional echocardiography and intravenous digital video subtraction angiography for diagnosis and evaluation of double aortic arch, 342
Perfusion, coronary
Quantitative assessment of infarct size reduction by coronary venous retroperfusion in baboons, 1425
Pericardial effusion
Echocardiographic study of right ventricular wall motion in cardiac tamponade, 1018
Pericarditis
Constrictive pericarditis as a complication of cardiac surgery: recognition of an entity, 742
Constrictive pericarditis: new aspects, 1014
Current incidence of postmyocardial infarction (Dressler's) syndrome, 1269
Immune reactions in tuberculous and chronic constrictive pericarditis. Clinical data and diagnostic significance of antimyocardial antibodies, 1007
Pharmacology
Task Force IV: pharmacologic interventions, 393
Phonocardiography
Hemodynamic determinants of the frequency and amplitude of a musical murmur produced by a regurgitant mitral bioprosthetic valve, 53
Pindolol
Variability of response to beta receptor blockade for angina pectoris in clinical trials: a study of pindolol, 722
Polymyositis
The heart and cardiac conduction system in polymyositis-dermatomyositis: a clinicopathologic study of 16 autopsied patients, 998
Pregnancy
Occlusive thromboaortopathy (Takayasu's disease) and pregnancy. Clinical course and management of 33 pregnancies and deliveries, 1293
Pregnancy and its outcome in women with and without surgical treatment of congenital heart disease, 641
Pregnancy in patients with a porcine valve bioprosthesis, 1051
Premature ventricular contractions
Prognostic implications of ventricular arrhythmias during 24 hour ambulatory monitoring in patients undergoing cardiac catheterization for coronary artery disease, 23
Procainamide
N-acetyl procainamide causing torsades de pointes, 1439
Termination of ventricular tachycardia: role of tachycardia cycle length, 1346
Use of procainamide in patients with the Wolff-Parkinson-White syndrome to disclose a short refractory period of the accessory pathway, 1087
Propranolol
Calcium channel blockade as primary therapy for stable angina pectoris. A double-blind placebo-controlled comparison of verapamil and propranolol, 1158
Comparative effects of abrupt withdrawal of propranolol and verapamil in angina pectoris, 1191
Comparison of oral propranolol and verapamil for combined systemic hypertension and angina pectoris. A placebo-controlled double-blind randomized crossover trial, 1164
Hemodynamic and clinical effects of combined verapamil and propranolol therapy in angina pectoris, 903
Hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients on propranolol, 704
Prolongation of the human cardiac monophasic action potential by sotalol, 1082
Reversal of regional myocardial depressant effects of propranolol with nitroglycerin, 478
Verapamil versus propranolol for angina at rest, 923
Prostacyclin
Prostacyclin therapy in patients with congestive heart failure, 320
Pulmonary arteries
Scintigraphic prediction of pulmonary arterial systolic pressure by regional right ventricular ejection fraction during the second half of systole, 1114
Two-dimensional echocardiographic identification of pulmonary artery branch stenosis, 814
Pulmonary disease
Augmentation of right ventricular performance in chronic obstructive pulmonary disease by terbutaline: a combined radionuclide and hemodynamic study, 313
Clinical problems of postoperative pulmonary vascular disease, 631
Physiologic correlates of right ventricular ejection fraction in chronic obstructive pulmonary disease: a combined radionuclide and hemodynamic study, 255
Pulmonary valve
Compression of intrapulmonary bronchi by abnormally branching pulmonary arteries associated with absent pulmonary valves, 804
Echocardiographic features of carcinoid heart disease, 762
Percutaneous balloon valuloplasty for pulmonic valve stenosis in the adult, 1442
Second operations for pulmonary stenosis or insufficiency after repair of tetralogy of Fallot, 637
Pulse
A simple teaching device for examination of the arterial and venous pulse, 1391

QRS complex
Ventricular activation during ventricular endocardial pacing. I. Electrocardiographic patterns related to the site of pacing, 1
Ventricular activation during ventricular endocardial pacing. II. Role of pace-mapping to localize origin of ventricular tachycardia, 11
Q-T interval
Influence of the autonomic nervous system on the Q-T interval in man, 1099
The QT > QS_2 syndrome: a new mortality risk indicator in coronary artery disease, 1229
Quinidine
Mechanism of additive effects of digoxin and quinidine on contractility in isolated cardiac muscle, 483

Radiation protection
Improved radiation protection for physicians performing cardiac catheterization, 1283
Radionuclide imaging
Gold-195m, a new generator-produced short-lived radionuclide for sequential assessment of ventricular performance by first pass radionuclide angiocardiography, 89
Improved radiation protection for physicians performing cardiac catheterization, 1283
Noninvasive assessment of myocardial contractility in asymptomatic patients with severe aortic regurgitation and normal left ventricular ejection fraction at rest, 45
Noninvasive detection of multivessel disease after myocardial infarction by exercise radionuclide ventriculography, 1242
Physiologic correlates of right ventricular ejection fraction in chronic obstructive pulmonary disease: a combined radionuclide and hemodynamic study, 255
Prospective evaluation of radionuclide angiocardiography for the diagnosis of coronary artery disease, 1212
Radionuclide evaluation of postextrasystolic potentiation of left ventricular function induced by atrial and ventricular stimulation, 106
Spontaneous changes in thallium-201 myocardial perfusion imaging after myocardial infarction, 1272
Risk factors
Importance of coronary risk factors in the presence or absence of myocardial ischemia, 1248
Plasma beta-thromboglobulin as a measure of platelet activity. Effect of risk factors and findings in ischemic heart disease and after acute myocardial infarction, 1258
The QT > QS_2 syndrome: a new mortality risk indicator in coronary artery disease, 1229
Rubidium-82
Relation between regional myocardial uptake of rubidium-82 and perfusion: absolute reduction of cation uptake in ischemia, 112
R wave
Increased R-wave amplitude induced by acute myocardial ischemia in the dog: a predictor of malignant ventricular arrhythmias, 844

Scintigraphy
An accurate means of detecting and characterizing abnormal patterns of ventricular activation by phase image analysis, 289
Cold pressor thallium-201 myocardial scintigraphy in the diagnosis of coronary artery disease, 1253
Detection of acute right ventricular infarction by right precordial electrocardiography, 421

Phase image characterization of ventricular contraction in left and right bundle branch block, 95
Use of QRS scoring and thallium-201 scintigraphy to assess left ventricular function after myocardial infarction, 1262
Sinus node
Electrophysiologic effects of flecainide acetate in patients with sinus nodal dysfunction, 1090
Situs inversus
Two-dimensional echocardiographic assessment of dextrocardia: a segmental approach, 1351
Sotalol
Prolongation of the human cardiac monophasic action potential by sotalol, 1082
Stenosis
Comparative effects of nitroglycerin and nifedipine on myocardial blood flow and contraction during flow-limiting coronary stenosis in the dog, 281
Hemodynamics of multiple versus single 50 percent coronary arterial stenoses, 276
Stimulation
Inter- and intraatrial dissociation during spontaneous atrial flutter: evidence for a focal origin of the arrhythmia, 756
Response to programmed ventricular stimulation: sensitivity, specificity and relation to heart disease, 452
S-T segment
Evaluation of normal variations in S-T segment patterns by body surface isopotential mapping: S-T segment elevation in absence of heart disease, 122
Sudden death
Can we prevent sudden cardiac death? 535
Characteristics of survivors of exertion- and nonexertion-related cardiac arrest: value of subsequent exercise testing, 671
Effects of sulfinpyrazone on ventricular vulnerability in the normal and the ischemic heart, 271
Long-term survival of patients with malignant ventricular arrhythmia treated with antiarrhythmic drugs, 437
Prediction of sudden death by electrophysiologic studies in high risk patients surviving acute myocardial infarction, 223
Prognostic implications of ventricular arrhythmias during 24 hour ambulatory monitoring in patients undergoing cardiac catheterization for coronary artery disease, 23
Sudden death in Prinzmetal's angina with coronary spasm documented by angiography. Analysis of three necropsy patients, 203
Ventricular fibrillation resulting from ischemia at a site remote from previous myocardial infarction. A conscious canine model of sudden coronary death, 1414
Sulfinpyrazone
Effects of sulfinpyrazone on ventricular vulnerability in the normal and the ischemic heart, 271
Sulfinpyrazone decreases epinephrine-induced platelet aggregation after myocardial infarction, 938
Surgery
Constrictive pericarditis as a complication of cardiac surgery: recognition of an entity, 742
Electrophysiologic residua and sequelae of surgery for congenital heart defects, 588
Inotropic contractile reserve: a useful predictor of increased 5 year survival and improved postoperative left ventricular function in patients with coronary artery disease and reduced ejection fraction, 39
Intraoperative 2-dimensional echocardiography: ejection of microbubbles from the left ventricle after cardiac surgery, 1130
Left and right ventricular adaptation to right ventricular overload before and after surgical repair of tetralogy of Fallot, 786
Long-term effects of prosthetic materials, 621
Surgical repair of congenitally corrected transposition of the great arteries: results and follow-up, 781
Surgery, aortocoronary bypass
Medical versus surgical treatment of unstable angina, 663
Surgery, coronary bypass
Continuous monitoring of left ventricular performance with the computerized nuclear probe during laryngoscopy and intubation before coronary artery bypass surgery, 735
Symposium on Postoperative Congenital Heart Disease in Adults
Clinical problems of postoperative pulmonary vascular disease, 631
Development and regression of increased ventricular mass, 605
Electrophysiologic residua and sequelae of surgery for congenital heart defects, 588
Epilogue, 655
Epilogue: Symposium on the Adult with Postoperative Congenital Heart Disease, 656
Epilogue: the pathologist, 652
Late results after operations for left ventricular outflow tract obstruction, 569
Long-term effects of prosthetic materials, 621
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560
Pregnancy and its outcome in women with and without surgical treatment of congenital heart disease, 641
Prologue, 543
Second operations for pulmonary stenosis or insufficiency after repair of tetralogy of Fallot, 637
Sequelae of atriotomy and ventriculotomy on the endocardium, conduction system and coronary arteries, 580
Ventricular performance in adults after operation for congenital heart disease, 612
World survey of the common cardiac malformations: developmental error or genetic variant? 544
Symposium on Verapamil Therapy for Angina Pectoris
Calcium channel blockade as primary therapy for stable angina pectoris. A double-blind placebo-controlled comparison of verapamil and propranolol, 1158
Clinical relevance of verapamil plasma levels in stable angina pectoris, 1180
Comparative effects of abrupt withdraw of propranolol and verapamil in angin pectoris, 1191
Comparison of oral propranolol and verapamil for combined systemic hypertension and angina pectoris. A placebo-controlled double-blind randomized crossover trial, 1164
Hemodynamic and clinical effects of combined verapamil and propranolol therapy in angina pectoris, 903
Long-term effectiveness of verapamil in stable and unstable angina pectoris. One-year follow-up of patients treate in placebo-controlled double-blind randomized clinical trials, 1185
Pharmacologic and hemodynamic mechanisms underlying the antiangin actions of verapamil, 886
Rationale for the choice of calcium antagonists in chronic stable angina. An objective double-blind placebo-controlled comparison of nifedipine and verapamil, 1173
Verapamil and digoxin: their respective effects on atrial fibrillation and their interaction, 894
Verapamil therapy for Prinzmetal's variant angina: comparison with placebo and nifedipine, 913
Verapamil therapy for stable and unstat angina pectoris: calcium channel antagonists in perspective, 881
Verapamil therapy for stable exertional angina pectoris, 1153
Verapamil therapy for unstable angina pectoris: review of double-blind placebo-controlled randomized clinic trials, 919
Verapamil versus propranolol for angin at rest, 923
Syncope
Electrophysiologic testing in the evaluation of patients with syncope o undetermined origin, 1309
Systolic time intervals
The isovolumic index: a new noninvasiv approach to the assessment of left ventricular function in man, 1401

Tachycardia
See also Ventricular tachycardia
Amiodarone for control of sustained ventricular tachyarrhythmia: clinical and electrophysiologic effects in 51 patients, 1066
A model of chronic ischemic arrhythmi the relation between electrically inducible ventricular tachycardia, ventricular fibrillation threshold and myocardial infarct size, 469
Antiarrhythmic, antifibrillatory, hemodynamic actions of bethanidine sulfate: an orally effective analog of bretylium for suppression of ventricu tachyarrhythmias, 728
Clinical and electrophysiologic findings patients with repetitive monomorphic ventricular tachycardia and otherwise normal electrocardiogram, 459
Comparison of the effects of placebo a encainide on programmed electrical stimulation and ventricular arrhythmi frequency, 305

Electrophysiologic drug testing in patients with malignant ventricular arrhythmias: importance of stimulation at more than 1 ventricular site, 1055
Electrophysiologic study for ventricular arrhythmia: effect on total and myocardial-specific creatine kinase activity, 1061
Onset of atrial fibrillation during antidromic tachycardia: association with sudden cardiac arrest and ventricular fibrillation in a patient with Wolff-Parkinson-White syndrome, 353
Quintuple pathways participating in three distinct types of atrioventricular reciprocating tachycardia in a patient with Wolff-Parkinson-White syndrome, 347
Role of electrophysiologic testing in managing patients who have ventricular tachycardia unrelated to coronary artery disease, 165
Termination of ventricular tachycardia: role of tachycardia cycle length, 1346
Ventricular activation during ventricular endocardial pacing. II. Role of pace-mapping to localize origin of ventricular tachycardia, 11

Technetium-99m pyrophosphate
Measurement of infarct size using single photon emission computed tomography and technetium-99m pyrophosphate: a description of the method and comparison with patient prognosis, 503

Telemetry
Task Force III: diagnostic procedures, 382

Teprotide
Coronary hemodynamic effects of angiotensin inhibition by captopril and teprotide in patients with congestive heart failure, 967

Terbutaline
Augmentation of right ventricular performance in chronic obstructive pulmonary disease by terbutaline: a combined radionuclide and hemodynamic study, 313

Tetralogy of Fallot
Compression of intrapulmonary bronchi by abnormally branching pulmonary arteries associated with absent pulmonary valves, 804
Early assessment of hemodynamic status after repair of tetralogy of Fallot: a comparison of 24 hour (intensive care unit) and 1 year postoperative data in 98 patients, 795
Left and right ventricular adaptation to right ventricular overload before and after surgical repair of tetralogy of Fallot, 786
Mechanism of acquired right ventricular outflow tract obstruction in patients with ventricular septal defect: an angiocardiographic study, 776
Second operations for pulmonary stenosis or insufficiency after repair of tetralogy of Fallot, 637

Thallium-201
Cold pressor thallium-201 myocardial scintigraphy in the diagnosis of coronary artery disease, 1253
Relation between regional distribution of thallium-201 and myocardial blood flow in normal, acutely ischemic, and infarcted myocardium, 1141
Serial right ventricular thallium-201 imaging after exercise: relation to anatomy of the right coronary artery, 1217
Spontaneous changes in thallium-201 myocardial perfusion imaging after myocardial infarction, 1272
Transaxial tomography with thallium-201 for detecting remote myocardial infarction. Comparison with planar imaging, 1236
Use of QRS scoring and thallium-201 scintigraphy to assess left ventricular function after myocardial infarction, 1262

Thrombolysis
Intracoronary thrombolysis in acute myocardial infarction: correlations among serum enzyme, scintigraphic and hemodynamic findings, 32
Intracoronary thrombolysis in acute myocardial infarction: duration of ischemia as a major determinant of late results after recanalization, 933

Tomography
Measurement of infarct size using single photon emission computed tomography and technetium-99m pyrophosphate: a description of the method and comparison with patient prognosis, 503
Relation between regional myocardial uptake of rubidium-82 and perfusion: absolute reduction of cation uptake in ischemia, 112
Transaxial tomography with thallium-201 for detecting remote myocardial infarction. Comparison with planar imaging, 1236

Torsades de pointes
N-acetyl procainamide causing torsades de pointes, 1439

Transposition of great arteries
Surgical repair of congenitally corrected transposition of the great arteries: results and follow-up, 781

Trauma
Two-dimensional echocardiographic findings in cardiac trauma, 1022

Tricuspid valve
Echocardiographic features of carcinoid heart disease, 762

Truncus arteriosus
Two-dimensional echocardiographic evaluation of persistent truncus arteriosus, 1376
Two-dimensional echocardiographic prospective diagnosis of common truncus arteriosus in infants, 1380

Tuberculosis
Immune reactions in tuberculous and chronic constrictive pericarditis. Clinical data and diagnostic significance of antimyocardial antibodies, 1007

T wave
Electrotonic modulation of the T wave and cardiac memory, 213
Electrotonic modulation of the T wave, 361
Transient T wave abnormalities in intermittent bundle branch block, 363

Valve prostheses
Hemodynamic determinants of the frequency and amplitude of a musical murmur produced by a regurgitant mitral bioprosthetic valve, 53
Long-term effects of prosthetic materials, 621
Pregnancy in patients with a porcine valve bioprosthesis, 1051

Valves, heart
Crisscrossed atrioventricular valves and prolonged survival, 1437

Vasodilators
Accuracy of cardiac output, oxygen uptake, and arteriovenous oxygen difference at rest, during exercise, and after vasodilator therapy in patients with severe, chronic heart failure, 973
Assessment of vasodilator therapy in patients with severe congestive heart failure: limitations of measurements of left ventricular ejection fraction and volumes, 954
Effects of acute and chronic minoxidil administration on rest and exercise hemodynamics and clinical status in patients with severe, chronic heart failure, 960

Ventricle, left
Assessment of left ventricular relaxation in patients with valvular regurgitation, 1028
Assessment of vasodilator therapy in patients with severe congestive heart failure: limitations of measurements of left ventricular ejection fraction and volumes, 954
Coronary collateral vessels: spectrum of physiologic capabilities with respect to providing rest and stress myocardial perfusion, maintenance of left ventricular function and protection against infarction, 230
Detection of left ventricular aneurysm on two dimensional echocardiography, 191
Echocardiographic-cineangiographic correlation in detecting left ventricular aneurysm: a prospective study of 422 patients, 337
Effect of beam directional alterations on left ventricular shortening fraction, 1120
Effect of changes in perfusion pressure on the position of the electrophysiologic border zone in acute regional ischemia in isolated perfused dog and pig hearts, 74
Effects of amyl nitrite on left ventricular relaxation in patients with borderline hypertension, 979
Epicardial activation of the human ventricle: effects of left ventricular hypertrophy, 1095
Gold-195m, a new generator-produced short-lived radionuclide for sequential assessment of ventricular performance by first pass radionuclide angiocardiography, 89
Inotropic contractile reserve: a useful predictor of increased 5 year survival and improved postoperative left ventricular function in patients with coronary artery disease and reduced ejection fraction, 39
Intraoperative 2-dimensional echocardiography: ejection of microbubbles from the left ventricle after cardiac surgery, 1130
Left ventricular end-systolic stress-shortening and stress-length relations in humans. Normal values and sensitivity to inotropic state, 1301

Limitations of comparing left ventricular volumes by two dimensional echocardiography, myocardial markers and cineangiography, 512
Nonobstructive hypertrophic cardiomyopathy: a precise assessment of hemodynamic characteristics and clinical implications, 990
Pathogenesis of left ventricular aneurysms: an experimental study in the rat model, 83
Prognostic significance of angiographically documented left ventricular aneurysm from the Coronary Artery Surgery Study (CASS), 157
Radionuclide evaluation of postextrasystolic potentiation of left ventricular function induced by atrial and ventricular stimulation, 106
The isovolumic index: a new noninvasive approach to the assessment of left ventricular function in man, 1401
Timing of operation for chronic aortic regurgitation, 325
Use of QRS scoring and thallium-201 scintigraphy to assess left ventricular function after myocardial infarction, 1262
Ventricular activation during ventricular endocardial pacing. I. Electrocardiographic patterns related to the site of pacing, 1

Ventricle, right
Augmentation of right ventricular performance in chronic obstructive pulmonary disease by terbutaline: a combined radionuclide and hemodynamic study, 313
Detection of acute right ventricular infarction by right precordial electrocardiography, 421
Echocardiographic study of right ventricular wall motion in cardiac tamponade, 1018
Mechanism of acquired right ventricular outflow tract obstruction in patients with ventricular septal defect: an angiocardiographic study, 776
Physiologic correlates of right ventricular ejection fraction in chronic obstructive pulmonary disease: a combined radionuclide and hemodynamic study, 255
Scintigraphic prediction of pulmonary arterial systolic pressure by regional right ventricular ejection fraction during the second half of systole, 1114
Serial right ventricular thallium-201 imaging after exercise: relation to anatomy of the right coronary artery, 1217
Two-dimensional echocardiographic assessment of right ventricular volumes in children with congenital heart disease, 1368

Ventricular arrhythmias
See also Arrhythmias
Amiodarone for control of sustained ventricular tachyarrhythmia: clinical and electrophysiologic effects in 51 patients, 1066
Antiarrhythmic effect of imipramine hydrochloride in patients with ventricular premature complexes without psychological depression, 172
Comparison of the effects of placebo and encainide on programmed electrical stimulation and ventricular arrhythmia frequency, 305
Electrophysiologic study for ventricular arrhythmia: effect on total and myocardial-specific creatine kinase activity, 1061
Increased R-wave amplitude induced by acute myocardial ischemia in the dog: a predictor of malignant ventricular arrhythmias, 844
Long-term survival of patients with malignant ventricular arrhythmia treated with antiarrhythmic drugs, 437
Pharmacokinetics of verapamil: experience with a sustained intravenous infusion regimen, 716
Prognostic implications of ventricular arrhythmias during 24 hour ambulatory monitoring in patients undergoing cardiac catheterization for coronary artery disease, 23

Ventricular fibrillation
A model of chronic ischemic arrhythmias: the relation between electrically inducible ventricular tachycardia, ventricular fibrillation threshold and myocardial infarct size, 469
Antiarrhythmic, antifibrillatory, hemodynamic actions of bethanidine sulfate: an orally effective analog of bretylium for suppression of ventricular tachyarrhythmias, 728
Characteristics of survivors of exertion- and nonexertion-related cardiac arrest: value of subsequent exercise testing, 671
Effects of sulfinpyrazone on ventricular vulnerability in the normal and the ischemic heart, 271
Electrophysiologic drug testing in patients with malignant ventricular arrhythmias: importance of stimulation at more than 1 ventricular site, 1055
Onset of atrial fibrillation during antidromic tachycardia: association with sudden cardiac arrest and ventricular fibrillation in a patient with Wolff-Parkinson-White syndrome, 353
Ventricular fibrillation resulting from ischemia at a site remote from previous myocardial infarction. A conscious canine model of sudden coronary death, 1414

Ventricular function
An accurate means of detecting and characterizing abnormal patterns of ventricular activation by phase image analysis, 289
Assessment of left ventricular relaxation in patients with valvular regurgitation, 1028
Augmentation of right ventricular performance in chronic obstructive pulmonary disease by terbutaline: a combined radionuclide and hemodynamic study, 313
Continuous monitoring of left ventricular performance with the computerized nuclear probe during laryngoscopy and intubation before coronary artery bypass surgery, 735
Coronary collateral vessels: spectrum of physiologic capabilities with respect to providing rest and stress myocardial perfusion, maintenance of left ventricular function and protection against infarction, 230
Development and regression of increased ventricular mass, 605
Effect of beam directional alterations on left ventricular shortening fraction, 1120
Effect of nifedipine on exercise-induced left ventricular dysfunction and myocardial hypoperfusion in stable angina, 689
Effects of amyl nitrite on left ventricular relaxation in patients with borderline hypertension, 979
Inotropic contractile reserve: a useful predictor of increased 5 year survival and improved postoperative left ventricular function in patients with coronary artery disease and reduced ejection fraction, 39
Intracoronary thrombolysis in acute myocardial infarction: duration of ischemia as a major determinant of late results after recanalization, 933
Left and right ventricular adaptation to right ventricular overload before and after surgical repair of tetralogy of Fallot, 786
Left ventricular end-systolic stress-shortening and stress-length relations in humans. Normal values a sensitivity to inotropic state, 1301
Local effects of electrical and mechanical stimulation on the recove properties of the canine ventricle, 26
Phase image characterization of ventricular contraction in left and righ bundle branch block, 95
Radionuclide evaluation of postextrasystolic potentiation of left ventricular function induced by atrial and ventricular stimulation, 106
Scintigraphic prediction of pulmonary arterial systolic pressure by regional right ventricular ejection fraction duri the second half of systole, 1114
The isovolumic index: a new noninvasiv approach to the assessment of left ventricular function in man, 1401
Ventricular performance and biochemic alteration of regional ischemic myocardium after reperfusion in the pig, 821
Ventricular performance in adults after operation for congenital heart disease 612

Ventricular hypertrophy
Development and regression of increas ventricular mass, 605

Ventricular septal defect
Long-term follow-up of patients with malformations for which definitive surgical repair has been available for 25 years or more, 560
Mechanism of acquired right ventricular outflow tract obstruction in patients with ventricular septal defect: an angiocardiographic study, 776

Ventricular stimulation
Response to programmed ventricular stimulation: sensitivity, specificity an relation to heart disease, 452

Ventricular tachycardia
See also Tachycardia
A model of chronic ischemic arrhythmi the relation between electrically inducible ventricular tachycardia, ventricular fibrillation threshold and myocardial infarct size, 469
Clinical and electrophysiologic findings patients with repetitive monomorphic ventricular tachycardia and otherwise normal electrocardiogram, 459

Electrophysiologic testing in the evaluation of patients with syncope of undetermined origin, 1309
Lack of effectiveness of oral mexiletine in patients with drug-refractory paroxysmal sustained ventricular tachycardia. A study utilizing programmed stimulation, 1075
Low energy countershock using an intravascular catheter in an acute cardiac care setting, 1124
Role of electrophysiologic testing in managing patients who have ventricular tachycardia unrelated to coronary artery disease, 165
Termination of ventricular tachycardia. Evaluation of a new pacing method, 1338
Termination of ventricular tachycardia: role of tachycardia cycle length, 1346

Ventricular volumes
Echocardiographic features of carcinoid heart disease, 762
Two-dimensional echocardiographic assessment of right ventricular volumes in children with congenital heart disease, 1368

Ventriculography
Digital intravenous ventriculography: analysis and validation of wall thickness changes during ischemia and inotropic stimulation in dogs, 874

Ventriculography, radionuclide
Noninvasive detection of multivessel disease after myocardial infarction by exercise radionuclide ventriculography, 1242

Verapamil
Calcium channel blockade as primary therapy for stable angina pectoris. A double-blind placebo-controlled comparison of verapamil and propranolol, 1158
Clinical relevance of verapamil plasma levels in stable angina pectoris, 1180
Comparative effects of abrupt withdrawal of propranolol and verapamil in angina pectoris, 1191
Comparison of oral propranolol and verapamil for combined systemic hypertension and angina pectoris. A placebo-controlled double-blind randomized crossover trial, 1164
Effects of verapamil on the electrophysiologic properties of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, 1323
Hemodynamic and clinical effects of combined verapamil and propranolol therapy in angina pectoris, 903
Hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients on propranolol, 704
Long-term effectiveness of verapamil in stable and unstable angina pectoris. One-year follow-up of patients treated in placebo-controlled double-blind randomized clinical trials, 1185
Long-term follow-up of verapamil and nitrate treatment for coronary artery spasm, 711
Pharmacokinetics of verapamil: experience with a sustained intravenous infusion regimen, 716
Pharmacologic and hemodynamic mechanisms underlying the antianginal actions of verapamil, 886
Randomized double-blind comparison of verapamil and nifedipine in chronic stable angina, 696
Rationale for the choice of calcium antagonists in chronic stable angina. An objective double-blind placebo-controlled comparison of nifedipine and verapamil, 1173
Verapamil and digoxin: their respective effects on atrial fibrillation and their interaction, 894
Verapamil therapy for Prinzmetal's variant angina: comparison with placebo and nifedipine, 913
Verapamil therapy for stable and unstable angina pectoris: calcium channel antagonists in perspective, 881
Verapamil therapy for stable exertional angina pectoris, 1153
Verapamil therapy for unstable angina pectoris: review of double-blind placebo-controlled randomized clinical trials, 919
Verapamil versus propranolol for angina at rest, 923

V wave
Large V waves in the pulmonary wedge pressure tracing in the absence of mitral regurgitation, 1044

Wolff-Parkinson-White syndrome
Effect of isoproterenol on the anterograde refractory period of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, 180
Effects of verapamil on the electrophysiologic properties of the accessory pathway in patients with the Wolff-Parkinson-White syndrome, 1323
Onset of atrial fibrillation during antidromic tachycardia: association with sudden cardiac arrest and ventricular fibrillation in a patient with Wolff-Parkinson-White syndrome, 353
Quintuple pathways participating in three distinct types of atrioventricular reciprocating tachycardia in a patient with Wolff-Parkinson-White syndrome, 347
Use of procainamide in patients with the Wolff-Parkinson-White syndrome to disclose a short refractory period of the accessory pathway, 1087

CONTENTS: VOLUME 50 • NUMBER 1 JULY

CLINICAL STUDIES

1 **Ventricular Activation During Ventricular Endocardial Pacing: I. Electrocardiographic Patterns Related to the Site of Pacing.** Harvey L. Waxman and Mark E. Josephson

11 **Ventricular Activation During Endocardial Pacing. II. Role of Pace-Mapping to Localize Origin of Ventricular Tachycardia.** Mark E. Josephson, Harvey L. Waxman, Michael E. Cain, Martin J. Gardner and Alfred E. Buxton

23 **Prognostic Implications of Ventricular Arrhythmias During 24 Hour Ambulatory Monitoring in Patients Undergoing Cardiac Catheterization for Coronary Artery Disease.** Robert M. Califf, Ray A. McKinnis, John Burks, Kerry L. Lee, Frank E. Harrell, Jr., Victor S. Behar, David B. Pryor, Galen S. Wagner and Robert A. Rosati

32 **Intracoronary Thrombolysis in Acute Myocardial Infarction: Correlations Among Serum Enzyme, Scintigraphic and Hemodynamic Findings.** Franz Schwarz, Gerhard Schuler, Hugo Katus, Helmuth C. Mehmel, Klaus von Olshausen, Manfred Hofmann, Hans-Joachim Herrmann and Wolfgang Kubler

39 **Inotropic Contractile Reserve: A Useful Predictor of Increased 5 Year Survival and Improved Postoperative Left Ventricular Function in Patients With Coronary Artery Disease and Reduced Ejection Fraction.** Richard W. Nesto, Lawrence H. Cohn, John J. Collins, Jr., Joshua Wynne, Leonard Holman and Peter F. Cohn

45 **Noninvasive Assessment of Myocardial Contractility in Asymptomatic Patients With Severe Aortic Regurgitation and Normal Left Ventricular Ejection Fraction at Rest.** Gerhard Schuler, Klaus von Olshausen, Franz Schwarz, Helmuth Mehmel, Manfred Hofmann, Hans-Joachim Hermann, Dieter Lange and Wolfgang Kübler, with the technical assistance of Cornelia Kehl

53 **Hemodynamic Determinants of the Frequency and Amplitude of a Musical Murmur Produced by a Regurgitant Mitral Bioprosthetic Valve.** Hani N. Sabbah, Donald J. Magilligan, Jr., Jeffrey B. Lakier and Paul D. Stein

59 **Partial Atrioventricular Canal Defect in Elderly Patients (Aged 60 Years or Older).** John K. Hynes, Abdul J. Tajik, James B. Seward and Dwight C. McGoon

EXPERIMENTAL STUDIES

63 **Spatial Distribution of (^{14}C)-Lidocaine and Blood Flow in Transmural and Lateral Border Zones of Ischemic Canine Myocardium.** Randolph E. Patterson, William S. Weintraub, Doris A. Halgash, Joseph Miao, John R. Rogers and Joel Kupersmith

74 **Effects of Changes in Perfusion Pressure on the Position of the Electrophysiologic Border Zone in Acute Regional Ischemia in Isolated Perfused Dog and Pig Hearts.** Michiel J. Janse and Francien Wilms-Schopman

83 **Pathogenesis of Left Ventricular Aneurysms: An Experimental Study in the Rat Model.** Judith S. Hochman and Bernadine Healy Bulkley

89 **Gold-195m, a New Generator-Produced Short-Lived Radionuclide for Sequential Assessment of Ventricular Performance by First Pass Radionuclide Angiography.** Frans J. Wackers, Robert W. Giles, Paul B. Hoffer, Robert C. Lange, Harvey J. Berger and Barry L. Zaret, with the technical assistance of Linda Pytlik and Michael Plankey

METHODS

95 **Phase Image Characterization of Ventricular Contraction in Left and Right Bundle Branch Block.** Michael A. Frais, Elias H. Botvinick, Dale W. Shosa, William J. O'Connell, Melvin M. Scheinman, Robert S. Hattner and Fred Morady

106 **Radionuclide Evaluation of Postextrasystolic Potentiation o Left Ventricular Function Induced by Atrial and Ventricula Stimulation.** Victor Kalff, William Chan, Mark Rabinovitch, Wil liam O'Neill, Joseph Walton, James Stewart, James H. Thrall an Bertram Pitt

112 **Relation Between Regional Myocardial Uptake of Rubidium-8 and Perfusion: Absolute Reduction of Cation Uptake in Isch emia.** Andrew P. Selwyn, Roger M. Allan, Antonio L'Abbate, Pete Horlock, Paolo Camici, John Clark, Harold A. O'Brien and Pete M. Grant

122 **Evaluation of Normal Variations in S-T Segment Patterns b Body Surface Isopotential Mapping: S-T Segment Elevation i Absence of Heart Disease.** David M. Mirvis

PEDIATRIC CARDIOLOGY

129 **Myocardial Injury in Infants With Congenital Heart Disease: Evaluation by Creatine Kinase MB Isoenzyme Analysis.** Robert J. Boucek, Alfred G. Kasselberg, Robert C. Boerth, Mark D. Parrish and Thomas P. Graham, Jr.

136 **Cardiac and Coronary Arterial Involvement in Infants and Children From New England With Mucocutaneous Lymph Node Syndrome (Kawasaki Disease). Angiographic-Echocardiographic Correlations.** Kyung J. Chung, Laura Brandt, David R. Fulton and Marshall B. Kreidberg

143 **Long-Term Follow-Up Study After Closure of Secundum Atrial Septal Defect in Children: An Echocardiographic Study.** Richard A. Meyer, Joan C. Korfhagen, Wesley Covitz and Samuel Kaplan

REPORTS ON HYPERTENSION

149 **Early Hypertension and Cardiac Work.** Gerald R. Dreslinski, Franz H. Messerli, Francis G. Dunn and Edward D. Frohlich

152 **Changes in R Wave Amplitude During Aerobic Exercise Stress Testing in Hypertensive Adolescents.** Bonita Falkner, David T. Lowenthal, Melton B. Affrime and Barbara Hamstra

COOPERATIVE STUDIES

157 **Prognostic Significance of Angiographically Documented Left Ventricular Aneurysm From the Coronary Artery Surgery Study (CASS).** David P. Faxon, Thomas J. Ryan, Kathryn B. Davis, Carolyn H. McCabe, William Myers, Jacques Lesperance, Richard Shaw and Terrance G. L. Tong

REPORTS ON THERAPY

165 **Role of Electrophysiologic Testing in Managing Patients Who Have Ventricular Tachycardia Unrelated to Coronary Artery Disease.** Gerald V. Naccarelli, Eric N. Prystowsky, Warren M. Jackman, James J. Heger, G. Thomas Rahilly and Douglas P. Zipes

172 **Antiarrhythmic Effect of Imipramine Hydrochloride in Patients With Ventricular Premature Complexes Without Psychological Depression.** Elsa-Grace V. Giardina and J. Thomas Bigger, Jr.

180 **Effect of Isoproterenol on the Anterograde Refractory Period of the Accessory Pathway in Patients With the Wolff-Parkinson-White Syndrome.** Hein J. J. Wellens, Pedro Brugada, Denis Roy, James Weiss and Frits W. Bär

DIAGNOSTIC SHELF

185 **Sensitivity and Specificity of M Mode Echocardiographic Signs of Mitral Valve Prolapse.** Maged Haikal, Martin A. Alpert, Richard B. Whiting, Masood Ahmad and Diana Kelly

191 **Detection of Left Ventricular Aneurysm on Two Dimensional Echocardiography.** Hans R. Baur, James A. Daniel and Richard R. Nelson

CASE REPORTS

197 **Postmyocardial Infarction Angina and Coronary Spasm.** Terrance J. Moran, William J. French, Howard F. Abrams and J. Michael Criley

203 **Sudden Death in Prinzmetal's Angina With Coronary Spasm Documented by Angiography.** William C. Roberts, R. Charles Curry, Jeffrey M. Isner, Bruce F. Waller, Bruce M. McManus, Renato Mariani-Constantini and Allan M. Ross

SPECIAL DEPARTMENTS

211 **Letters to the Editor**

212 **Instructions for Authors**

CONTENTS: VOLUME 50 • NUMBER 2 AUGUST

CLINICAL STUDIES

213 **Electronic Modulation of the T Wave and Cardiac Memory.** Mauricio B. Rosenbaum, Horacio H. Blanco, Marcelo V. Elizari, Julio O. Lazzari and Jorge M. Davidenko

223 **Prediction of Sudden Death by Electrophysiologic Studies in High Risk Patients Surviving Acute Myocardial Infarction.** Angas Hamer, Jitu Vohra, David Hunt and Graeme Sloman

230 **Coronary Collateral Vessels: Spectrum of Physiologic Capabilities With Respect to Providing Rest and Stress Myocardial Perfusion, Maintenance of Left Ventricular Function and Protection Against Infarction.** Albert J. Kolibash, Charles A. Bush, Richard A. Wepsic, David P. Schroeder, Marc R. Tetalman and Richard P. Lewis

239 **Myocardial Metabolic Alterations After Contrast Angiography.** Judith A. Wisneski, Edward W. Gertz, Richard Neese, Whai-Jen Soo, J. David Bristow, James R. Adams and J. Pierre Beaudry

246 **Cardiac Effects of Prolonged and Intense Exercise Training in Patients With Coronary Artery Disease.** Ali A. Ehsani, Wade H. Martin III, Gregory W. Heath and Edward F. Coyle

255 **Physiologic Correlates of Right Ventricular Ejection Fraction in Chronic Obstructive Pulmonary Disease: A Combined Radionuclide and Hemodynamic Study.** Bruce N. Brent, Harvey J. Berger, Richard Matthay, Donald Mahler, Linda Pytlik and Barry L. Zaret

EXPERIMENTAL STUDIES

263 **Local Effects of Electrical and Mechanical Stimulation on the Recovery Properties of the Canine Ventricle.** Boaz Avitall, Herbert J. Levine, Shapur Naimi, Richard P. Donahue, Stephen G. Pauker and Dan Adam

271 **Effects of Sulfinpyrazone on Ventricular Vulnerability in the Normal and Ischemic Heart.** Ernst A. Raeder, Richard L. Verrier and Bernard Lown

276 **Hemodynamics of Multiple Versus Single 50 Percent Coronary Arterial Stenoses.** Hani N. Sabbah and Paul D. Stein

281 **Comparative Effects of Nitroglycerin and Nifedipine on Myocardial Blood Flow and Contraction During Flow-Limiting Coronary Stenosis in the Dog.** William S. Weintraub, Satoshi Akizuki, Jai B. Agarwal, Monty M. Bodenheimer, Vidya S. Banka and Richard H. Helfant

METHODS

289 **An Accurate Means of Detecting and Characterizing Abnormal Patterns of Ventricular Activation by Phase Image Analysis.** Elias H. Botvinick, Michael A. Frais, Dale W. Shosa, John W. O'Connell, Jose A. Pacheco-Alvarez, Melvin Scheinman, Robert S. Hattner, Frederick Morady and Donald B. Faulkner

299 **Factors Influencing Estimated Oxygen Uptake During Exercise Testing Soon After Myocardial Infarction.** William Haskell, William Savin, Neil Oldridge and Robert DeBusk

REPORTS ON THERAPY

305 **Comparison of the Effects of Placebo and Encainide on Programmed Electrical Stimulation and Ventricular Arrhythmia Frequency.** Henry J. Duff, Dan M. Roden, Albert K. Dawson, John A. Oates, Raphael F. Smith and Raymond L. Woosley

313 **Augmentation of Right Ventricular Performance in Chronic Obstructive Pulmonary Disease by Terbutaline: A Combined Radionuclide and Hemodynamic Study.** Bruce N. Brent, Donald Mahler, Harvey J. Berger, Richard A. Matthay, Linda Pytlik and Barry L. Zaret

320 **Prostacyclin Therapy in Patients With Congestive Heart Failure.** Yoshiki Yui, Hisayoshi Nakajima, Chuichi Kawai and Tomoyuki Murakami

REVIEWS

325 **Timing of Operation for Chronic Aortic Regurgitation.** Robert O. Bonow, Douglas R. Rosing, Kenneth M. Kent and Stephen E. Epstein

DIAGNOSTIC SHELF

337 **Echocardiographic-Cineangiographic Correlation in Detecting Left Ventricular Aneurysm: A Prospective Study of 422 Patients.** Cees A. Visser, Gerard Kan, George K. David, Kong Ing Lie and Dirk Durrer

342 **Two Dimensional Echocardiography and Intravenous Digital Video Subtraction Angiography for Diagnosis and Evaluation of Double Aortic Arch.** David J. Sahn, Lilliam M. Valdes-Cruz, Theron W. Ovitt, Gerald Pond, Robert Mammana, Stanley J. Goldberg, Hugh D. Allen and Jack G. Copeland

347 **Quintuple Pathways Participating in Three Distinct Types of Atrioventricular Reciprocating Tachycardia in a Patient With Wolff-Parkinson-White Syndrome.** Bolivar Portillo, Nelly Portillo-Leon, Liaqat Zaman and Agustin Castellanos

CASE REPORTS

353 **Onset of Atrial Fibrillation During Antidromic Tachycardia: Association With Sudden Cardiac Arrest and Ventricular Fibrillation in a Patient With Wolff-Parkinson-White Syndrome.** Francisco G. Cosio, D. Woodrow Benson, Jr., Robert W. Anderson, William T. Hession, Marc R. Pritzker and David G. Benditt

SPECIAL DEPARTMENTS

360 **Instructions to Authors**

EDITORIALS

361 **Electrotonic Modulation of the T Wave.** Brian F. Hoffman

363 **Transient T Wave Abnormalities in Intermittent Bundle Branch Block.** Borys Surawicz

BETHESDA CONFERENCE REPORT

365 **Thirteenth Bethesda Conference: Emergency Cardiac Care**

CONTENTS: VOLUME 50 • NUMBER 3 SEPTEMBE

CLINICAL STUDIES

421 **Detection of Acute Right Ventricular Infarction by Right Precordial Electrocardiography.** Charles H. Croft, Pascal Nicod, James R. Corbett, Samuel E. Lewis, Robert Huxley, Jhulan Mukharji, James T. Willerson and Robert E. Rude

428 **Clinical Implications of Anterior S-T Segment Depression in Patients With Acute Inferior Myocardial Infarction.** Charles H. Croft, Wayne Woodward, Pascal Nicod, James R. Corbett, Samuel E. Lewis, James T. Willerson and Robert E. Rude

437 **Long-Term Survival of Patients With Malignant Ventricular Arrhythmia Treated With Antiarrhythmic Drugs.** Thomas B. Graboys, Bernard Lown, Philip J. Podrid and Regis DeSilva

444 **Perioperative Coronary Arterial Spasm: Long-Term Follow-Up.** Alfred E. Buxton, John W. Hirshfeld, Jr., William J. Untereker, Sheldon Goldberg, Alden H. Harken, Larry W. Stephenson and Richard N. Edie

452 **Response to Programmed Ventricular Stimulation: Sensitivity, Specificity, and Relation to Heart Disease.** Frank D. Livelli, Jr., J. Thomas Bigger, Jr., James A. Reiffel, Eli S. Gang, J. Norman Patton, Patricia M. Noethling, Linda M. Rolnitzky and Jerry I. Gliklich

459 **Clinical and Electrophysiologic Findings in Patients With Repetitive Monomorphic Ventricular Tachycardia and Otherwise Normal Electrocardiogram.** G. Thomas Rahilly, Eric N. Prystowsky, Douglas P. Zipes, Gerald V. Naccarelli, Warren M. Jackman and James J. Heger

EXPERIMENTAL STUDIES

469 **A Model of Chronic Ischemic Arrhythmias: The Relation Between Electrically Inducible Ventricular Tachycardia, Ventricular Fibrillation Threshold and Myocardial Infarct Size.** Eli S. Gang, J. Thomas Bigger, Jr. and Frank D. Livelli

478 **Reversal of Regional Myocardial Depressant Effects of Propranolol With Nitroglycerin.** Shigehito Hattori, Vidya S. Banka, Jai B. Agarwal, Hajime Yamazaki, Monty M. Bodenheimer and Richard H. Helfant

483 **Mechanism of Additive Effects of Digoxin and Quinidine on Contractility in Isolated Cardiac Muscle.** Ray E. Lash, Russell C. Reeves, David N. S. Reeves and Lloyd L. Hefner

488 **Effects of Hypertension on Cardiac Performance in Rats With Myocardial Infarction.** Peter J. Fletcher, Janice M. Pfeffer, Marc A. Pfeffer and Eugene Braunwald

497 **Regional Myocardial Lidocaine Concentration Following Continuous Intravenous Infusion Early and Late After Myocardial Infarction.** Ruben A. Zito, Vicente J. Caride, Theodore Holford and Barry L. Zaret

METHODS

503 **Measurement of Infarct Size Using Single Photon Emission Computed Tomography and Technetium-99m Pyrophosphate: A Description of the Method and Comparison With Patient Prognosis.** B. Leonard Holman, Samuel Z. Goldhaber, Carl-Martin Kirsch, Joseph F. Polak, Bruce J. Friedman, Robert J. English and Joshua Wynne

512 **Limitations of Comparing Left Ventricular Volumes by Two Dimensional Echocardiography, Myocardial Markers and Cineangiography.** Ingela Schnittger, Peter J. Fitzgerald, George T. Daughters, Neil B. Ingels, Niki E. Kantrowitz, Anne Schwarzkopf, Carol W. Mead and Richard L. Popp

520 **Quantitation and Significance of Horizontal Cardiac Motion in M Mode and Two Dimensional Echocardiography.** Kenneth M. Kessler, Kyriacos Pefkaros, Rafael Sequeira and Robert J. Myerburg

EDITORIALS

535 **Can We Prevent Sudden Cardiac Death?** Leonard N. Horowi and Joel Morganroth

539 **Emergency Cardiac Care—Bootstrapping to 2,000 AD.** Ga J. Anderson and Max Harry Weil

540 **Instructions to Authors**

SYMPOSIUM ON POSTOPERATIVE CONGENITAL HEART DISEASE IN ADULTS

Mary Allen Engle and Joseph K. Perloff, Guest Editors

541 **Dedication.** Mary Allen Engle and Joseph K. Perloff

542 **Remarks.** Helen B. Taussig

543 **Prologue.** Mary Allen Engle and Joseph K. Perloff

544 **World Survey of the Common Cardiac Malformations: Deve opmental Error or Genetic Variant?** Helen B. Taussig

560 **Long-Term Follow-Up of Patients With Malformations for Whic Definitive Surgical Repair Has Been Available for 25 Years More.** Dan G. McNamara and Larry A. Latson

569 **Late Results After Operations for Left Ventricular Outflow Tra Obstruction.** Michael Jones, Glenn R. Barnhart and Andrew Morrow

580 **Sequelae of Atriotomy and Ventriculotomy on the Endocardiun Conduction System and Coronary Arteries.** Saroja Bharati ar Maurice Lev

588 **Electrophysiologic Residua and Sequelae of Surgery for Co genital Heart Defects.** Victoria L. Vetter and Leonard Horowitz

605 **Development and Regression of Increased Ventricular Mas** Joseph K. Perloff

612 **Ventricular Performance in Adults After Operation for Co genital Heart Disease.** Thomas P. Graham, Jr.

621 **Long-Term Effects of rosthetic Materials.** Dwight McGoon

631 **Clinical Problems of Postoperative Pulmonary Vascular Di ease.** William F. Friedman and Miriam F. Heiferman

637 **Second Operations for Pulmonary Stenosis or Insufficienc After Repair of Tetralogy of Fallot.** Paul A. Ebert

641 **Pregnancy and Its Outcome in Women With and Without Su gical Treatment of Congenital Heart Disease.** Ruth Whittemor John C. Hobbins and Mary Allen Engle

652 **Epilogue: The Pathologist.** Jesse E. Edwards

655 **Epilogue.** John W. Kirklin

656 **Epilogue: Symposium on the Adult With Postoperative Co genital Heart Disease.** Alexander S. Nadas

BRIEF REPORTS

658 **Embolus to the Left Main Coronary Artery.** Bruce F. Walle Douglas S. Dixon, Rak W. Kim and William C. Roberts

SPECIAL DEPARTMENTS

661 **Letters**

662 **Books Received**

Index to Advertisers on pages A 158 and A 159

CONTENTS: VOLUME 50 • NUMBER 4 OCTOBER

CLINICAL STUDIES

663 **Medical Versus Surgical Treatment of Unstable Angina.** Herbert N. Hultgren, Udipi R. Shettigar, and D. Craig Miller

671 **Characteristics of Survivors of Exertion- and Nonexertion-Related Cardiac Arrest: Value of Subsequent Exercise Testing.** W. Douglas Weaver, Leonard B. Cobb, and Alfred P. Hallstrom

677 **Quantitative Comparison of Extent of Coronary Narrowing and Size of Healed Myocardial Infarct in 33 Necropsy Patients With Clinically Recognized and in 28 Necropsy Patients With Clinically Unrecognized ("Silent") Previous Acute Myocardial Infarction.** Henry Scott Cabin and William C. Roberts

682 **Anatomic and Prognostic Implications of an Early Positive Treadmill Test.** Ricky M. Schneider, John F. Seaworth, Mary L. Dohrmann, Robert M. Lester, Harry R. Phillips, Thomas M. Bashore, and John T. Baker

689 **Effect of Nifedipine on Exercise-Induced Left Ventricular Dysfunction and Myocardial Hypoperfusion in Stable Angina.** Nadim M. Zacca, Mario Verani, Robert A. Chahine, and Richard R. Miller

696 **Randomized Double-Blind Comparison of Verapamil and Nifedipine in Chronic Stable Angina.** V. Bala Subramanian, Michael J. Bowles, Nardev Singh Khurmi, Anthony B. Davies, and Edward B. Raftery

704 **Hemodynamic and Electrophysiologic Effects of Verapamil and Nifedipine in Patients on Propranolol.** Michael D. Winniford, Roy V. Markham, Brian G. Firth, Pascal Nicod, and L. David Hillis

711 **Long-Term Follow-Up of Verapamil and Nitrate Treatment for Coronary Artery Spasm.** S. Benedict Freedman, David R. Richmond, and David T. Kelly

716 **Pharmacokinetics of Verapamil: Experience With a Sustained Intravenous Infusion Regimen.** Michael J. Reiter, David G. Shand, Linda M. Aanonsen, Robert Wagoner, Elizabeth McCarthy, and Edward L. C. Pritchett

722 **Variability of Response to Beta-Receptor Blockade for Angina Pectoris in Clinical Trials: A Study of Pindolol.** William E. Harston and Gottlieb C. Friesinger

728 **Antiarrhythmic, Antifibrillatory, and Hemodynamic Actions of Bethanidine Sulfate: An Orally Effective Analog of Bretylium for Suppression of Ventricular Tachyarrhythmia.** Marvin B. Bacaner and David G. Benditt

735 **Continuous Monitoring of Left Ventricular Performance With the Computerized Nuclear Probe During Laryngoscopy and Intubation Before Coronary Artery Bypass Surgery.** Robert W. Giles, Harvey J. Berger, Paul G. Barash, Sanjiwan Tarabadkar, Peter G. Marx, Graeme L. Hammond, Alexander S. Geha, Hillel Laks, and Barry L. Zaret

742 **Constrictive Pericarditis as a Complication of Cardiac Surgery: Recognition of an Entity.** Michael A. Kutcher, Spencer B. King III, Benjamin N. Alimurung, Joseph M. Carver, and R. Bruce Logue

749 **Increased Physical Activity: A Protective Factor Against Heart Attacks in Puerto Rico.** Mario R. Garcia-Palmieri, Raul Costas, Jr., Mercedes Cruz-Vidal, Paul D. Sorlie, and Richard J. Havlik

756 **Inter- and Intraatrial Dissociation During Spontaneous Atrial Flutter: Evidence for a Focal Origin of the Arrhythmia.** Peter L. Friedman, Pedro Brugada, Karl-Heinz Kuck, Denis Roy, Jeronimo Farre, Frits W. H. M. Bär, and Hein J. J. Wellens

762 **Echocardiographic Features of Carcinoid Heart Disease.** John A. Callahan, Edmund M. Wroblewski, Guy S. Reeder, William D. Edwards, James B. Seward, and Abdul J. Tajik

PEDIATRIC CARDIOLOGY

769 **Exercise Electrocardiogram, Blood Pressure, and Working Capacity in Young Patients With Valvular or Discrete Subvalvular Aortic Stenosis.** Frederick W. James, David C. Schwartz, Samuel Kaplan, and Steve P. Spilkin

776 **Mechanism of Acquired Right Ventricular Outflow Tract Obstruction in Patients With Ventricular Septal Defect: An Angiocardiographic Study.** Giacomo Pongiglione, Robert M. Freedom, David Cook, and Richard D. Rowe

781 **Surgical Repair of Congenitally Corrected Transposition of the Great Arteries: Results and Follow-Up.** Betau Hwang, Frederick Bowman, James Malm, and Ehud Krongrad

786 **Left and Right Ventricular Adaptation to Right Ventricular Overload Before and After Surgical Repair of Tetralogy of Fallot.** Peter E. Lange, Dietrich G. W. Onnasch, Alexander Bernhard, and Paul H. Heintzen

795 **Early Assessment of Hemodynamic Status After Repair of Tetralogy of Fallot: A Comparison of 24 Hour (Intensive Care Unit) and 1 Year Postoperative Data in 98 Patients.** Peter Lang, Carl W. Chipman, Harold Siden, Roberta G. Williams, William I. Norwood, and Aldo R. Castaneda

800 **Pediatric Cardiac Catheterization With Same-Day Discharge.** J. Deane Waldman, Terrance S. Young, Stanley J. Pappelbaum, Searle W. Turner, Stanley E. Kirkpatrick, and Lily M. George

804 **Compression of Intrapulmonary Bronchi by Abnormally Branching Pulmonary Arteries Associated With Absent Pulmonary Valves.** Marlene Rabinovitch, Stafford Grady, Ivan David, Richard Van Praagh, Ursula Sauer, Konrad Buhlmeyer, Aldo R. Castaneda, and Lynn Reid *with the technical assistance of* Donna K. Silva

814 **Two-Dimensional Echocardiographic Identification of Pulmonary Artery Branch Stenosis.** David D. Tinker, Navin C. Nanda, J. Peter Harris, and James A. Manning

EXPERIMENTAL STUDIES

821 **Ventricular Performance and Biochemical Alteration of Regional Ischemic Myocardium After Reperfusion in the Pig.** Marvin L. Murphy, Chun Fu Peng, James J. Kane, and Karl D. Straub

829 **Effect of Intraaortic Balloon Counterpulsation on Regional Myocardial Blood Flow and Oxygen Consumption in the Presence of Coronary Artery Stenosis: Observations in an Awake Animal Model.** Henry Gewirtz, William Ohley, David O. Williams, Ying Sun, and Albert S. Most

838 **Detection of Ischemic Myocardium in Vivo Through the Chest Wall by Quantitative Ultrasonic Tissue Characterization.** Randolph D. Cohen, Jack G. Mottley, James G. Miller, Peter B. Kurnick, and Burton E. Sobel

844 **Increased R-Wave Amplitude Induced by Acute Myocardial Ischemia in the Dog: A Predictor of Malignant Ventricular Arrhythmias.** Daniel David, Eric L. Michelson, Masahito Naito, Mark Schaffenburg, and Leonard S. Dreifus

849 **Ibuprofen-Mediated Infarct Size Reduction: Effects on Regional Myocardial Function in Canine Myocardial Infarction.** Philip C. Kirlin, Joseph L. Romson, Bertram Pitt, Gerald D. Abrams, M. Anthony Schork, and Benedict R. Lucchesi

857 **Protective Effects on Isolated Hearts With Developing Infarction: Slow Channel Blockade by Diltiazem Versus Beta-Adrenoceptor Antagonism by Metoprolol.** Christian W. Hamm, Francis T. Thandroyen, and Lionel H. Opie

864 **Inhibition of Hypoxic Pulmonary Vasoconstriction by Nifedipine.** Thomas Kennedy and Warren Summer

869 **Effects of Angiographic Contrast Medium on Isolated Canine Coronary Arteries.** Hector Lardani, Gustavo Rinaldi, and Horacio Cingolani

874 **Digital Intravenous Ventriculography: Analysis and Validation of Wall Thickness Changes During Ischemia and Inotropic Stimulation in Dogs.** Robert A. Slutsky, Kenneth H. Gerber, and Charles B. Higgins, *with the technical assistance of* Frank H. Haigler and Fred G. Werner

SYMPOSIUM ON VERAPAMIL THERAPY FOR ANGINA PECTORIS

MILTON PACKER, Guest Editor, and WILLIAM H. FRISHMAN, Guest Co-Editor

881 **Verapamil Therapy for Stable and Unstable Angina Pectoris: Calcium Channel Antagonists in Perspective.** Milton Packer and William H. Frishman

PART I: PHARMACOLOGIC AND HEMODYNAMIC ACTIONS AND INTERACTIONS

886 **Pharmacologic and Hemodynamic Mechanisms Underlying the Antianginal Actions of Verapamil.** Bramah N. Singh, Christopher Y. C. Chew, Martin A. Josephson, and Milton Packer

894 **Verapamil and Digoxin: Their Respective Effects On Atrial Fibrillation and Their Interaction.** Herman O. Klein and Eliese Kaplinsky

903 **Hemodynamic and Clinical Effects of Combined Verapamil and Propranolol Therapy in Angina Pectoris.** Milton Packer, Martin B. Leon, Robert O. Bonow, Joshua Kieval, Douglas R. Rosing, and V. Bala Subramanian

PART II: STUDIES IN ANGINA AT REST

913 **Verapamil Therapy for Prinzmetal's Variant Angina: Comparison With Placebo and Nifedipine.** Michael D. Winniford, Stacey M. Johnson, David R. Mauritson, James S. Rellas, Gregory A. Redish, James T. Willerson, and L. David Hillis

919 **Verapamil Therapy for Unstable Angina Pectoris: Review of Double-Blind Placebo-Controlled Randomized Clinical Trials.** Jawahar Mehta and C. Richard Conti

923 **Verapamil Versus Propranolol for Angina at Rest.** Oberdan Parodi, Ignazio Simonetti, Antonio L'Abbate, and Attilio Maseri

SPECIAL DEPARTMENTS

929 **Letters**

Instructions to Authors on page A157

CONTENTS: VOLUME 50 • NUMBER 5 NOVEMBER

CLINICAL STUDIES

933 **Intracoronary Thrombolysis in Acute Myocardial Infarction: Duration of Ischemia as a Major Determinant of Late Results After Recanalization.** Franz Schwarz, Gerhard Schuler, Hugo Katus, Manfred Hofmann, Joachim Manthey, Harald Tillmanns, Helmuth C. Mehmel, and Wolfgang Kübler

938 **Sulfinpyrazone Decreases Epinephrine-Induced Platelet Aggregation After Myocardial Infarction.** Jean-Gilles Latour, Pierre Theroux, and Martial G. Bourassa

945 **Familial Aggregation of Coronary Heart Disease and Its Relation to Known Genetic Risk Factors.** Leo P. ten Kate, Helge Boman, Stephen P. Daiger, and Arno G. Motulsky

954 **Assessment of Vasodilator Therapy in Patients With Severe Congestive Heart Failure: Limitations of Measurements of Left Ventricular Ejection Fraction and Volumes.** Brian G. Firth, Gregory J. Dehmer, Roy V. Markham, Jr., James T. Willerson, and L. David Hillis

960 **Effects of Acute and Chronic Minoxidil Administration on Rest and Exercise Hemodynamics and Clinical Status in Patients With Severe, Chronic Heart Failure.** Mark Nathan, Stanley A. Rubin, Deirdre Siemienczuk, and H.J.C. Swan

967 **Coronary Hemodynamic Effects of Angiotensin Inhibition by Captopril and Teprotide in Patients With Congestive Heart Failure.** Jonathan L. Halperin, David P. Faxon, Mark A. Creager, Theodore A. Bass, Caroline D. Melidossian, Haralambos Gavras, and Thomas J. Ryan

973 **Accuracy of Cardiac Output, Oxygen Uptake, an Arteriovenous Oxygen Difference at Rest, During Exercise, and After Vasodilator Therapy in Patients With Severe, Chronic Heart Failure.** Stanley Rubin, Deirdre Siemienczuk, Mark D. Nathan, Joann Prause, and H.J.C. Swan

979 **Effects of Amyl Nitrite on Left Ventricular Relaxation in Patients With Borderline Hypertension.** Charles Z. Naggar, Kenneth Stanley, and Lori L. Downing

985 **Significance of Abnormal Electrocardiograms in Highly Trained Athletes.** David G. Oakley and Celia M. Oakley

990 **Nonobstructive Hypertrophic Cardiomyopathy: A Precise Assessment of Hemodynamic Characteristics and Clinical Implications.** Yuzo Hirota, Koichi Furubayashi, Kiyotaka Kaku, Gen Shimizu, Masaya Kino, Keishiro Kawamura, and Tadasu Takatsu

998 **The Heart and Cardiac Conducting System in Polymyositis-Dermatomyositis: A Clinicopathologic Study of 16 Autopsied Patients.** Helen M. Haupt, and Grover M. Hutchins

1007 **Immune Reactions in Tuberculous and Chronic Constrictive Pericarditis. Clinical Data and Diagnostic Significance of Antimyocardial Antibodies.** Bernhard Maisch, Stefanie Maisch, and Kurt Kochsiek

1014 **Constrictive Pericarditis: New Aspects.** Noble O. Fowler

1018 **Echocardiographic Study of Right Ventricular Wall Motion in Cardiac Tamponade.** Peter J. Engel, Henry Hon, Noble O. Fowler, and Sandi Plummer

1022 **Two-Dimensional Echocardiographic Findings in Cardiac Trauma.** Fletcher A. Miller, Jr., James B. Seward, Bernard Gersh, Abdul J. Tajik, and Peter Mucha, Jr.

1028 **Assessment of Left Ventricular Relaxation in Patients With Valvular Regurgitation.** Michel F. Rousseau, Hubert Pieur, André A. Charlier, and Lucien A. Brasseur

1037 **Detection of Mild Aortic Regurgitation by Range-Gated Pulsed Doppler Echocardiography.** Ricardo J. Esper

1044 **Large V Waves in the Pulmonary Wedge Pressure Tracing in the Absence of Mitral Regurgitation.** Augusto D. Pichard, Richard Kay, Harry Smith, Peter Rentrop, James Holt, and Richard Gorlin

1051 **Pregnancy in Patients With a Porcine Valve Bioprosthesis.** Uberto Bortolotti, Aldo Milano, Allessandro Mazzucco, Carlo Valfre, Rosario Russo, Marialuisa Valente, Luciano Schivazappa, Gaetano Thiene, and Vincenzo Gallucci

ELECTROPHYSIOLOGIC STUDIES

1055 **Electrophysiologic Drug Testing in Patients With Malignant Ventricular Arrhythmias: Importance of Stimulation at More Than 1 Ventricular Site.** Fred Morady, David Hess, and Melvin M. Scheinman

1061 **Electrophysiologic Study for Ventricular Arrhythmia: Effect on Total and Myocardial-Specific Creatine Kinase Activity.** Francis E. Marchlinski, Harvey L. Waxman, Leslie M. Shaw, Marilyn D. Ezri, and Mark E. Josephson

1066 **Amiodarone for Control of Sustained Ventricular Tachyarrhythmia: Clinical and Electrophysiologic Effects in 51 Patients.** Harvey L. Waxman, William C. Groh, Francis E. Marchlinski, Alfred E. Buxton, Laura M. Sadowski, Leonard N. Horowitz, Mark E. Josephson, and John A. Kastor

1075 **Lack of Effectiveness of Oral Mexiletine in Patients With Drug-Refractory Paroxysmal Sustained Ventricular Tachycardia. A Study Utilizing Programmed Stimulation.** Edwin V. Palileo, William Welch, Julie Hoff, Boris Strasberg, Robert A. Bauernfeind, Steven Swiryn, Aldo Coelho, and Kenneth M. Rosen

1082 **Prolongation of the Human Cardiac Monophasic Action Potential by Sotalol.** Debra S. Echt, Larry E. Berte, William T. Clusin, Rolf G. Samuelsson, Donald C. Harrison, and Jay W. Mason

1087 **Use of Procainamide in Patients With the Wolff-Parkinson-White Syndrome to Disclose a Short Refractory Period of the Accessory Pathway.** Hein J. J. Wellens, Simon Braat, Pedro Brugada, Anton P. M. Gorgels, and Frits W. Bär

1090 **Electrophysiologic Effects of Flecainide Acetate in Patients With Sinus Nodal Dysfunction.** Harald Vik-Mo, Ole-Jørgen Ohm, and Per Lund-Johansen

1095 **Epicardial Activation of the Human Ventricle: Effects of Left Ventricular Hypertrophy.** Isaac Weiner, Bruce Mindich, and Roberta Pitchon

1099 **Influence of the Autonomic Nervous System on the Q-T Interval in Man.** Kevin F. Browne, Douglas P. Zipes, James J. Heger, and Eric N. Prystowsky

1104 **Subcostal M-Mode Echocardiography of the Right Atrial Wall in the Diagnosis of Cardiac Arrhythmias.** Niksa Drinkovic

METHODS

1109 **Application of Body Surface Mapping to Exercise Testing: S-T_{80} Isoarea Maps in Patients With Coronary Artery Disease.** Frank G. Yanowitz, G. Michael Vincent, Robert L. Lux, Mahesh Merchant, Larry S. Green, and J. A. Abildskov

1114 **Scintigraphic Prediction of Pulmonary Arterial Systolic Pressure by Regional Right Ventricular Ejection Fraction During the Second Half of Systole.** Bruce J. Friedman and B. Leonard Holman

1120 **Effect of Beam Directional Alterations on Left Ventricular Shortening Fraction.** Heinz R. Hoenecke, Jr., Stanley J. Goldberg, David J. Sahn, Hugh D. Allen, and Lilliam M. Valdes-Cruz

1124 **ow Energy Countershock Using an Intravascular Catheter an Acute Cardiac Care Setting.** Raymond Yee, Douglas P. s, Sajad Gulamhusein, Michael J. Kallok, and George J.

1130 **Intraoperative 2-Dimensional Echocardiography: Ejection of Microbubbles From the Left Ventricle After Cardiac Surgery.** Paul C. Rodigas, Frances J. Meyer, George B. Haasler, Jerome M. Dubroff, and Henry M. Spotnitz

EXPERIMENTAL STUDIES

1133 **Impaired Collateral Blood Flow Reserve Early After Nontransmural Myocardial Infarction in Conscious Dogs.** Randolph E. Patterson, Beverly A. Jones-Collins, and Roger Aamodt

1141 **Relation Between Regional Distribution of Thallium-201 and Myocardial Blood Flow in Normal, Acutely Ischemic, and Infarcted Myocardium.** Alan Chu, Robert H. Murdock, Jr., and Frederick R. Cobb

HISTORICAL STUDIES

1145 **Jacob Mendez DaCosta: Medical Teacher, Clinician, and Clinical Investigator.** Charles F. Wooley

EDITORIALS

1149 **Hypothesis: Is Congestive Cardiomyopathy Caused by a Hyperreactive Myocardial Microcirculation (Microvascular Spasm)?** Stephen M. Factor and Edmund H. Sonnenblick

SYMPOSIUM ON VERAPAMIL THERAPY FOR ANGINA PECTORIS. PART III: STUDIES IN EFFORT-RELATED ANGINA

MILTON PACKER, Guest Editor, and WILLIAM H. FRISHMAN, Guest Co-Editor

1153 **Verapamil Therapy for Stable Exertional Angina Pectoris.** Donald A. Weiner and Michael D. Klein

1158 **Calcium Channel Blockade as Primary Therapy for Stable Angina Pectoris. A Double-Blind Placebo-Controlled Comparison of Verapamil and Propranolol.** V. Bala Subramanian, Michael J. Bowles, Anthony B. Davies, and Edward B. Raftery

1164 **Comparison of Oral Propranolol and Verapamil for Combined Systemic Hypertension and Angina Pectoris. A Placebo-Controlled Double-Blind Randomized Crossover Trial.** William H. Frishman, Neal A. Klein, Philip Klein, Joel A. Strom, Robert Tawil, Roger Strair, Bowen Wong, Steven Roth, Thierry H. LeJemtel, Simcha Pollack, and Edmund H. Sonnenblick

1173 **Rationale for the Choice of Calcium Antagonists in Chronic Stable Angina. An Objective Double-Blind Placebo-Controlled Comparison of Nifedipine and Verapamil.** V. Bala Subramanian, Michael J. Bowles, Nardev S. Khurmi, Anthony B. Davies, and Edward B. Raftery

1180 **Clinical Relevance of Verapamil Plasma Levels in Stable Angina Pectoris.** William Frishman, Edward Kirsten, Michael Klein, Michael Pine, Stacey M. Johnson, L. David Hillis, Milton Packer, and Robert Kates

1185 **Long-Term Effectiveness of Verapamil in Stable and Unstable Angina Pectoris. One-Year Follow-Up of Patients Treated in Placebo-Controlled Double-Blind Randomized Clinical Trials.** Stephen Scheidt, William H. Frishman, Milton Packer, Jawahar Mehta, Oberdan Parodi, and V. Bala Subramanian

1191 **Comparative Effects of Abrupt Withdrawal of Propranolol and Verapamil in Angina Pectoris.** William H. Frishman, Neal Klein, Joel Strom, Martin N. Cohen, Harry Shamoon, Howard Willens, Philip Klein, Steven Roth, Louis Iorio, Thierry LeJemtel, Simcha Pollack, and Edmund H. Sonnenblick

SPECIAL DEPARTMENTS

1196 **Instructions to Authors**

1197 **Letters**

CORONARY HEART DISEASE

1199 **Effects of Carbon Dioxide, Nd-YAG, and Argon Laser Radiation on Coronary Atheromatous Plaques.** George S. Abela, Sigurd Normann, Donald Cohen, Robert L. Feldman, Edward A. Geiser, and C. Richard Conti

1206 **Transluminal Laser Catheter Angioplasty.** Daniel S. J. Choy, Simon Stertzer, Heidrun Z. Rotterdam, Nigel Sharrock, and Ivan P. Kaminow

1209 **Laser Coronary Angioplasty: Experience With 9 Cadaver Hearts.** Daniel S. J. Choy, Simon H. Stertzer, Heidrun Z. Rotterdam, and Michael S. Bruno

1212 **Prospective Evaluation of Radionuclide Angiocardiography for the Diagnosis of Coronary Artery Disease.** Erle H. Austin, Frederick R. Cobb, R. Edward Coleman, and Robert H. Jones

1217 **Serial Right Ventricular Thallium-201 Imaging After Exercise: Relation to Anatomy of the Right Coronary Artery.** Kenneth A. Brown, Charles A. Boucher, Robert D. Okada, H. William Strauss, Kenneth A. McKusick, and Gerald M. Pohost

1223 **Enhanced Transcardiac l-Norepinephrine Response During Cold Pressor Test in Obstructive Coronary Artery Disease.** Hiltrud S. Mueller, Parinam S. Rao, Pulipaka B. Rao, Dennis J. Gory, J. Gerard Mudd, and Stephen M. Ayres

1229 **The QT $>QS_2$ Syndrome: A New Mortality Risk Indicator in Coronary Artery Disease.** Harisios Boudoulas, Young Ho Sohn, William O'Neill, Roger Brown, and Arnold M. Weissler

1236 **Transaxial Tomography With Thallium-201 for Detecting Remote Myocardial Infarction. Comparison With Planar Imaging.** James L. Ritchie, David L. Williams, George Harp, John L. Stratton, and James H. Caldwell

1242 **Noninvasive Detection of Multivessel Disease After Myocardial Infarction by Exercise Radionuclide Ventriculography.** Alan G. Wasserman, Richard J. Katz, Patricia Cleary, Vijay M. Varma, Richard C. Reba, and Allan M. Ross

1248 **Importance of Coronary Risk Factors in the Presence or Absence of Myocardial Ischemia.** Markku Heliövaara, Martti J. Karvonen, Sven Punsar, and Jaason Haapakoski

1253 **Cold Pressor Thallium-201 Myocardial Scintigraphy in the Diagnosis of Coronary Artery Disease.** Masood Ahmad, Jerzy P. Dubiel, and Helmut Haibach

1258 **Plasma Beta-Thromboglobulin as a Measure of Platelet Activity. Effect of Risk Factors and Findings in Ischemic Heart Disease and After Acute Myocardial Infarction.** Charles W. Pumphrey and Joan Dawes

1262 **Use of QRS Scoring and Thallium-201 Scintigraphy to Assess Left Ventricular Function After Myocardial Infarction.** Nicholas L. DePace, Abdulmassih S. Iskandrian, A-Hamid Hakki, Sally A. Kane, and Bernard L. Segal

1269 **Current Incidence of Postmyocardial Infarction (Dressler's) Syndrome.** Edgar Lichstein, Edward Arsura, Gerald Hollander, Alvin Greengart, and Michael Sanders

1272 **Spontaneous Changes in Thallium-201 Myocardial Perfusion Imaging After Myocardial Infarction.** Andrew J. Buda, James D. Dubbin, Ian L. MacDonald, Hans D. Strauss, Sally A. Orr, and Harry Meindok

1279 **Assessment of the Use of the Age- and Sex-Specific United States Population as a Control Group for Analysis of Survival in Coronary Artery Disease.** Robert M. Califf, Kerry L. Lee, Frank E. Harrell, Jr., Sue Y. S. Kimm, Seymour Grufferman, and Robert A. Rosati

MISCELLANEOUS TOPICS

1283 **Improved Radiation Protection for Physicians Performin Cardiac Catheterization.** Edward W. Gertz, Judith A. Wisneski Robert G. Gould, and John R. Akin

1287 **Compression of the Superior Vena Cava and Right Atrium i Cardiac Tamponade.** Stephen W. Miller, Laura Feldman, Igo Palacios, Robert E. Dinsmore, John B. Newell, Linda Gillam and Arthur E. Weyman

1293 **Occlusive Thromboaortopathy (Takayasu's Disease) an Pregnancy. Clinical Course and Management of 3 Pregnancies and Deliveries.** Kaichiro Ishikawa and Shumpe Matsuura

1301 **Left Ventricular End-Systolic Stress-Shortening and Stress Length Relations in Humans. Normal Values and Sensitivit to Inotropic State.** Kenneth M. Borow, Laurence H. Green William Grossman, and Eugene Braunwald

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1309 **Electrophysiologic Testing in the Evaluation of Patients With Syncope of Undetermined Origin.** David S. Hess, Fred Morady, and Melvin M. Scheinman

1316 **Value of the H-Q Interval in Patients With Bundle Branch Block and the Role of Prophylactic Permanent Pacing.** Melvin M. Scheinman, Robert W. Peters, Mary Jane Sauvé, Jawahar Desai, Joseph A. Abbott, John Cogan, Barry Wohl, and Katherine Williams

1323 **Effects of Verapamil on the Electrophysiologic Properties of the Accessory Pathway in Patients With the Wolff-Parkinson-White Syndrome.** Richard W. Harper, Eric Whitford, Ken Middlebrook, Jack Federman, Stan Anderson, and Aubrey Pitt

1331 **Atrial Excitability and Conduction in Patients With Interatrial Conduction Defects.** Ross J. Simpson, Jr., James R. Foster, and Leonard S. Gettes

1338 **Termination of Ventricular Tachycardia. Evaluation of a New Pacing Method.** Martin J. Gardner, Harvey L. Waxman, Alfred E. Buxton, Michael E. Cain, and Mark E. Josephson

1346 **Termination of Ventricular Tachycardia: Role of Tachycardia Cycle Length.** Denis Roy, Harvey L. Waxman, Alfred E. Buxton, Francis E. Marchlinski, Michael E. Cain, Martin J. Gardner, and Mark E. Josephson

CONGENITAL HEART DISEASE

1351 **Two-Dimensional Echocardiographic Assessment of Dextrocardia: A Segmental Approach.** James C. Huhta, Donald J. Hagler, James B. Seward, Abdul J. Tajik, Paul R. Julsrud, and Donald G. Ritter

1361 **Conotruncal Malformations: Diagnosis in Infancy Using Subxiphoid 2-Dimensional Echocardiography.** Stephen P. Sanders, Fredrick Z. Bierman, and Roberta G. Williams

1368 **Two-Dimensional Echocardiographic Assessment of Right Ventricular Volume in Children With Congenital Heart Disease.** Satoshi Hiraishi, Thomas G. DiSessa, Jay M. Jarmakani, Toshi Nakanishi, Josephine B. Isabel-Jones, and William F. Friedm *With the technical assistance of* Barbara Sternlight

1376 **Two-Dimensional Echocardiographic Evaluation of Pe nt Truncus Arteriosus.** José Marin-Garcia and Ina L. D.

1380 **Two-Dimensional Echocardiographic Prospective osis of Common Truncus Arteriosus in Infants.** Thom Riggs Sue and Milton H. Paul *with the technical assis* Pajcic

1385 **Two-Dimensional Echocardiographic Features of Interruption of the Aortic Arch.** Thomas W. Riggs, Teresa E. Berry, Kalim U. Aziz, and Milton H. Paul

METHODS

1391 **A Simple Teaching Device for Examination of the Arterial and Venous Pulse.** Arthur Kreitenburg, Joel S. Karliner, Robert L. Engler, and E. Roger Marchand

1394 **Evaluation of Pulmonary and Systemic Blood Flow by 2-Dimensional Doppler Echocardiography Using Fast Fourier Transform Spectral Analysis.** Stanley J. Goldberg, David J. Sahn, Hugh D. Allen, Lilliam M. Valdes-Cruz, Heinz Hoenecke, and Yvonne Carnahan

1401 **The Isovolumic Index: A New Noninvasive Approach to the Assessment of Left Ventricular Function in Man.** G. B. John Mancini, Dennis Costello, Valmik Bhargava, Wilbur Lew, Martin LeWinter, and Joel S. Karliner

EXPERIMENTAL STUDIES

1409 **Exercise-Induced Decrease in Flow Through Stenotic Coronary Arteries in the Dog.** Jeffrey S. Schwartz, Bruce Tockman, Jay N. Cohn, and Robert J. Bache

1414 **Ventricular Fibrillation Resulting From Ischemia at a Site Remote From Previous Myocardial Infarction. A Conscious Canine Model of Sudden Coronary Death.** Eugene Patterson, Kurt Holland, Brian T. Eller, and Benedict R. Lucchesi

1424 **Quantitative Assessment of Infarct Size Reduction by Coronary Venous Retroperfusion in Baboons.** Grayson G. Geary, Gregory T. Smith, Glen T. Suehiro, Charles Zeman, Benjamin Siu, and J. Judson McNamara

HISTORICAL STUDIES

1431 **Tribute to Paul Wood.** E. Grey Dimond

1433 **The Early Pathophysiologic Understanding of Angina Pectoris.** Paul Kligfield

BRIEF REPORTS

1436 **Crisscrossed Atrioventricular Valves and Prolonged Survival.** William C. Roberts, Thomas L. Spray, Richard J. Shemin, and Barry J. Maron

1439 **N-Acetyl Procainamide Causing Torsades de Pointes.** Brian Olshansky, James Martins, and Scott Hunt

With the automated Cinescope III TG™ generator, the only thing you change is the patient.

The Cinescope III TG generator from Picker International sizes up your angiography patients—automatically. Because it's totally automated, through microprocessor technology. To give you proper image density and contrast—regardless of the size and build of your patient.

Turn it on in the morning. And all day long you'll get the power, rapid exposure rate and automatic exposure controls you need for consistently excellent diagnostic films. You'll also get feedback and analysis of the image system itself, with continuous display of both technique factors and function.

And because it's computerized, Cinescope III TG gives y synchronization of film a devices with X-ray produ Computerization also ma ideal for digital interfaci

What it all adds up to up time for you. Reduce time. Reduced patient ex And dependable image q Study after study after st

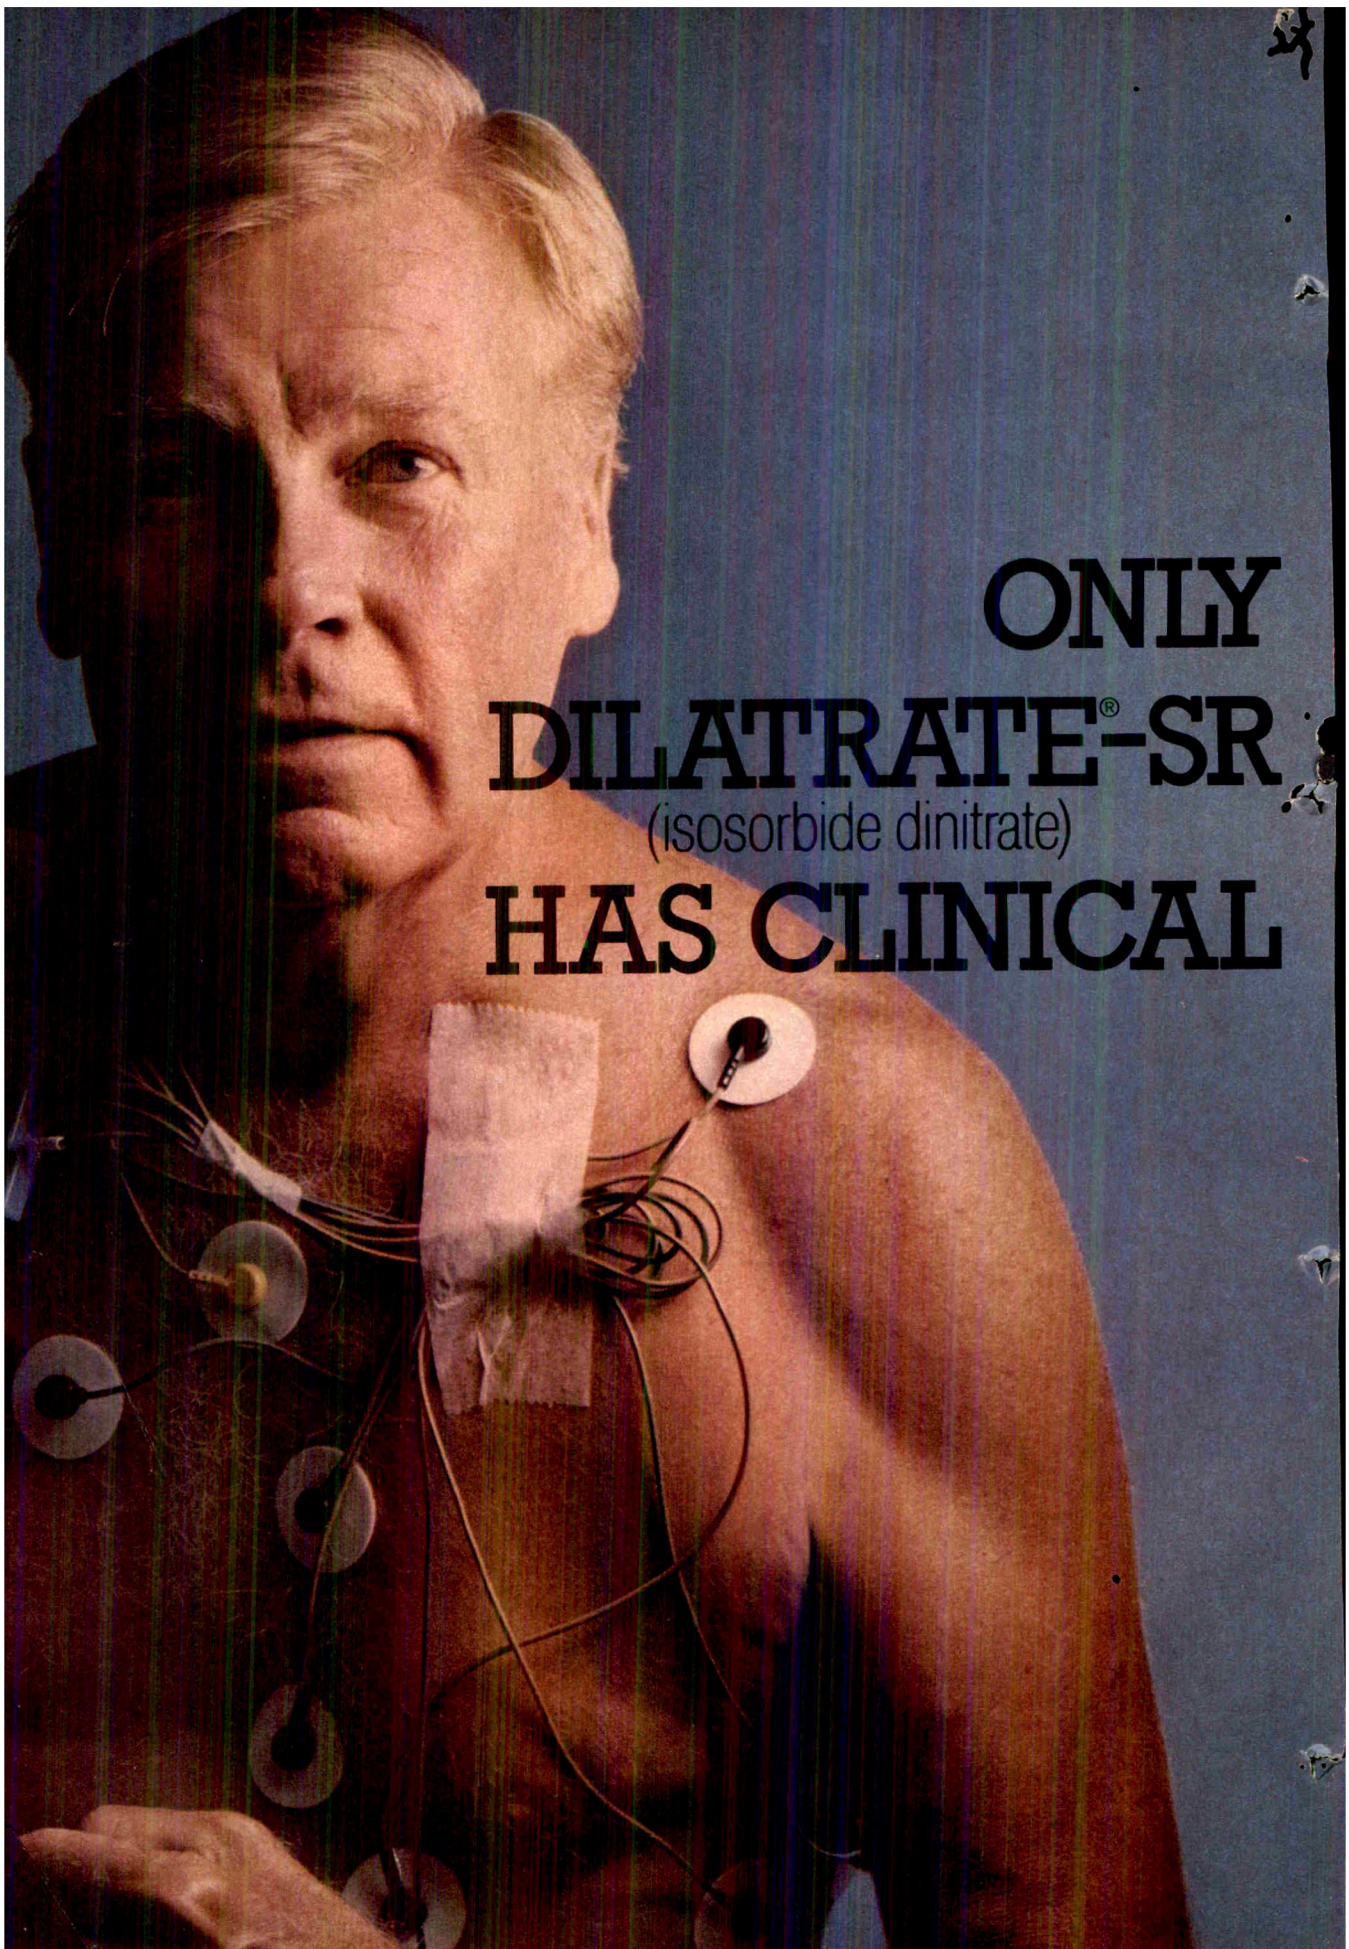
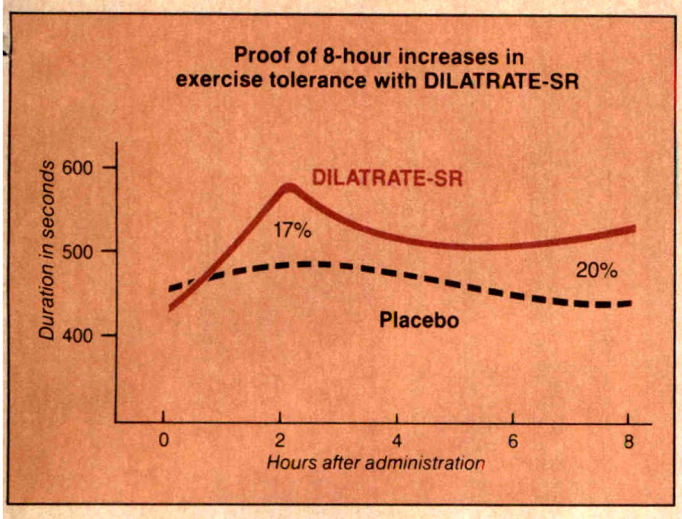
PICKER INTERNATIC



ONLY
DILATRATE®-SR
(isosorbide dinitrate)
HAS CLINICAL

In treadmill tests, DILATRATE-SR produced a 17% increase in mean total exercise duration within 2 hours; after 8 hours the increase was 20%.



*Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patie with chronic stable angina, significant improvement in exe cise capacity was sustained for eight hours following admi istration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness f a full eight hours. And, the advantage over placebo did no appear to be decreasing at the end of eight hours.

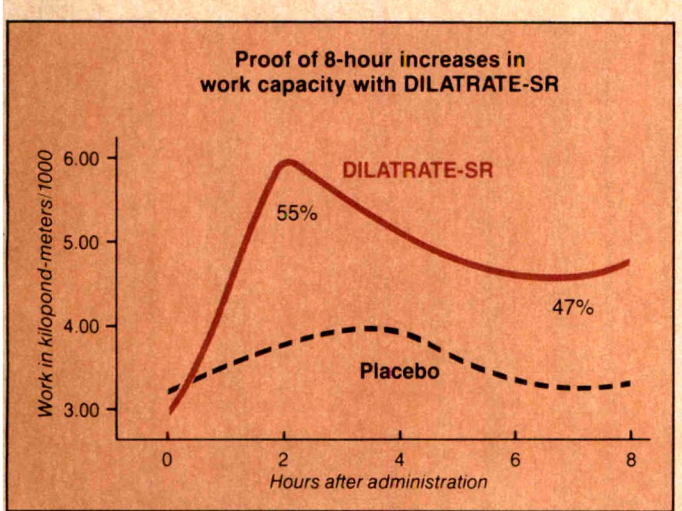
Increases in exercise tolerance translate into true patient benefits

Exercise tolerance tests provide objective measurements improvement in work capacity that can be correlated with t anginal patient's daily activities. These results demonstrat that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

Clinical support of plasma level studies

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

PROOF: 8-hour antianginal activity*



A 20% increase in duration of treadmill exercise means another minute or two at higher speed on a steeper incline. When mean work performance was calculated, DILATRATE-SR provided a 47% increase at 8 hours.

A unique method of delivering isosorbide dinitrate

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN a a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

DILATRATE-SR simplifies antianginal therapy

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

*Please see brief summary of full prescribing information o following page. For full prescribing information, consult package insert.

Dilatrate®-SR
(isosorbide dinitrate) 40 mg

The clinically confirmed CONFIDENCE CAPSULE

Dilatrate®-SR
(isosorbide dinitrate) 40 mg

BRIEF SUMMARY

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATION: Idiosyncrasy to this drug.

WARNINGS: Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

PRECAUTIONS: Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

ADVERSE REACTIONS: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

For full prescribing information, consult package insert.

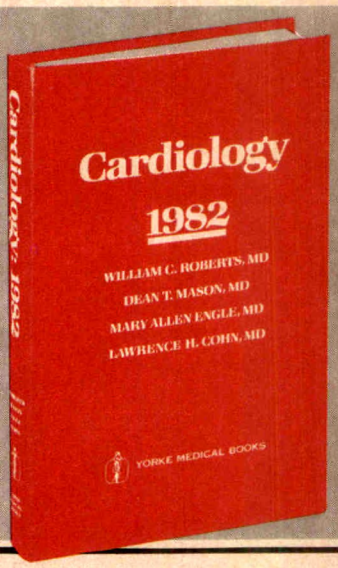
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

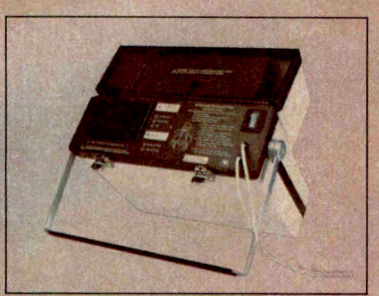
Announcing the dawn
of a new era in the treatment
of sudden cardiac arrest

The first automated, external defibrillator/pacemaker

HEART AID™



Designed to help protect the high-risk patient at home or work

An automatic, portable device for use by trained family members and coworkers before the ambulance arrives, when every minute counts.

- □ electronic detection and analysis of respiration and ECG
- □ microcircuitry diagnosis of ventricular fibrillation, potentially lethal tachycardia, asystole, profound bradycardia
- □ automatic initiation of defibrillating shocks or pacing stimuli
- □ Company-provided training program (using certified CPR instructors) at your hospital or patient's home

In treating out-of-hospital cardiac arrest, the earlier that defibrillation is accomplished, the greater the chance for survival.*

*Eisenberg MS, Hallstrom A, Bergner L: Long-term survival after out-of-hospital cardiac arrest. *N Engl J Med* 306:1340-1343, 1982.

DIGITALIS TOXICITY
– and how to avoid it in CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF furosemide

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.

But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic*.

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.

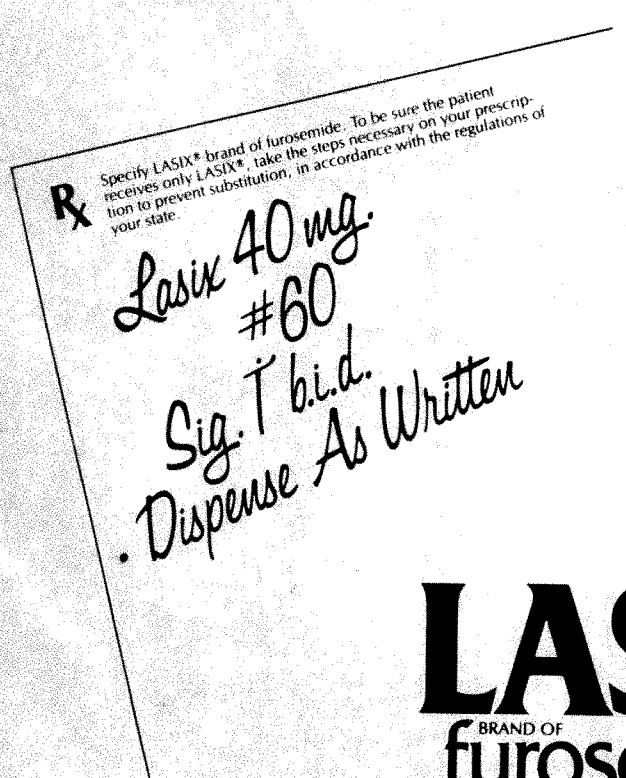
Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration... and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.



If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

Reference: 1. Koch H: Drugs most frequently used in office-based practice: National Ambulatory Medical Care Survey, 1980, Vital and Health Statistics of the Nat Ctr for Health Statistics, No. 78 (May 12) 1982.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

LASIX®

TABLETS: 20, 40 & 80 mg

BRAND OF furosemide

The diuretic of choice for the digitalized patient.

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

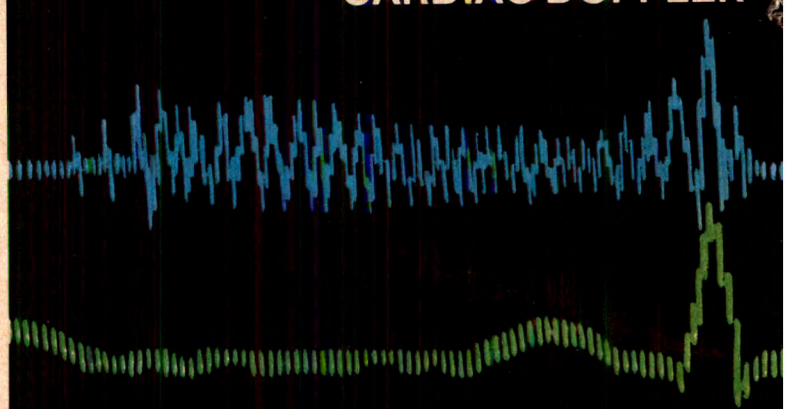
Evaluate heart valve abnormalities safely and effectively with noninvasive Cardiac Doppler.

Sonacolor® CD
CARDIAC DOPPLER



The Sonacolor CD system uses real time spectral display of continuous wave Doppler ultrasound signals to provide high quality diagnostic information on blood flow through all four heart valves. Doppler flow velocity signals are detected and the spectrum is displayed in color and in real time.

This simple, noninvasive system evaluates the amount of leakage through incompetent valves and provides an estimation of pressure drop in stenotic valves. In addition, it has the potential for evaluating blood flow velocity through coronary grafts and shunts.

Each valve has a different characteristic pattern that can be easily recognized and varying degrees of abnormalities are readily identified.

Also displayed is an ECG trace for time reference and a phonocardiograph trace for correlation of heart sounds with the Doppler flow velocity patterns. Measurement cursors can be positioned at various points to quantitate useful heart and valve performance indices.

CARDIOLOGISTS

Private Practice Opportunities Tailor-Made For You.

Deciding upon the community where your skills are in the greatest demand can be an arduous task. Your choice is important to your career, and Humana, with more than 89 hospitals nationwide, can help you to select the location that best suits your professional and personal needs.

Furthermore, Humana can assist you in establishing a private practice. Whether you desire a solo, group or associate arrangement, Humana can make it happen. And, in many cases, financial assistance is available.

Humana offers you a wealth of choices from which to choose and currently we have outstanding Cardiology opportunities in the following states:

- Alabama
- Florida
- Georgia
- Virginia
- Texas
- Kentucky
- West Virginia

So get moving. For further information, send your curriculum vitae to the address below, or call Gordon Crawford, Manager Professional Relations, TOLL-FREE at 800-626-1590. There is no obligation. Humana, The Hospital Company, Dept. M-12, 1800 First National Tower, Louisville, Kentucky 40201.

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, Univer. of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine

SEPTEMBER 1978, 288 PAGES, 110 ILLUS, 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

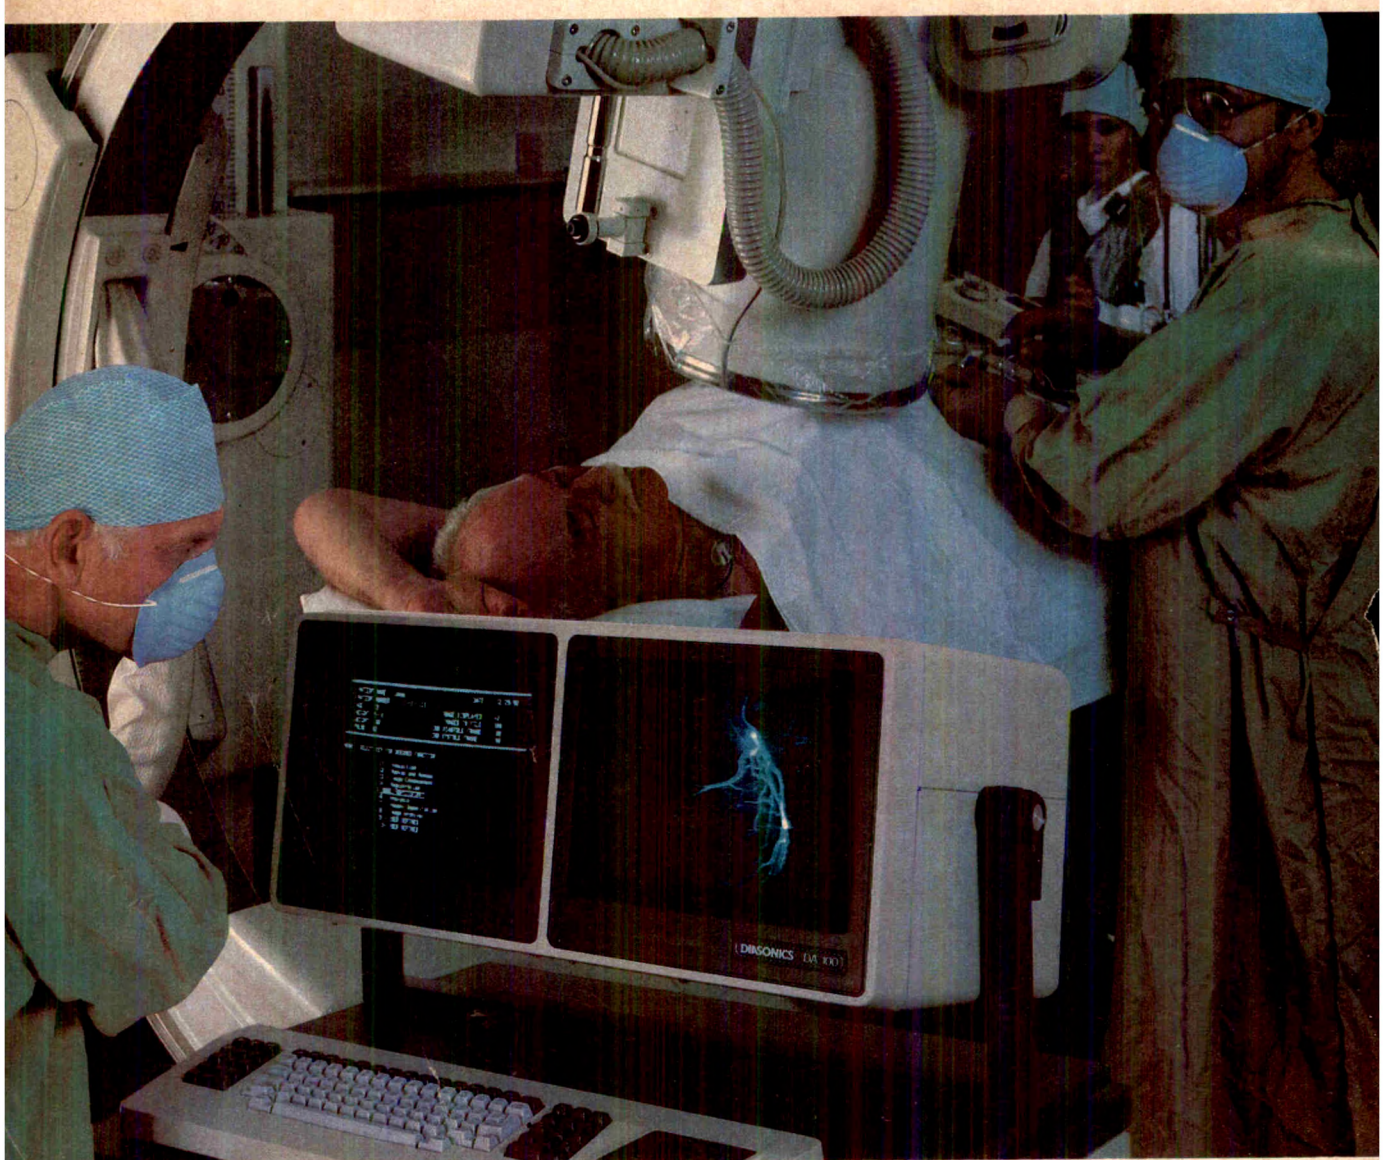
DIASONICS

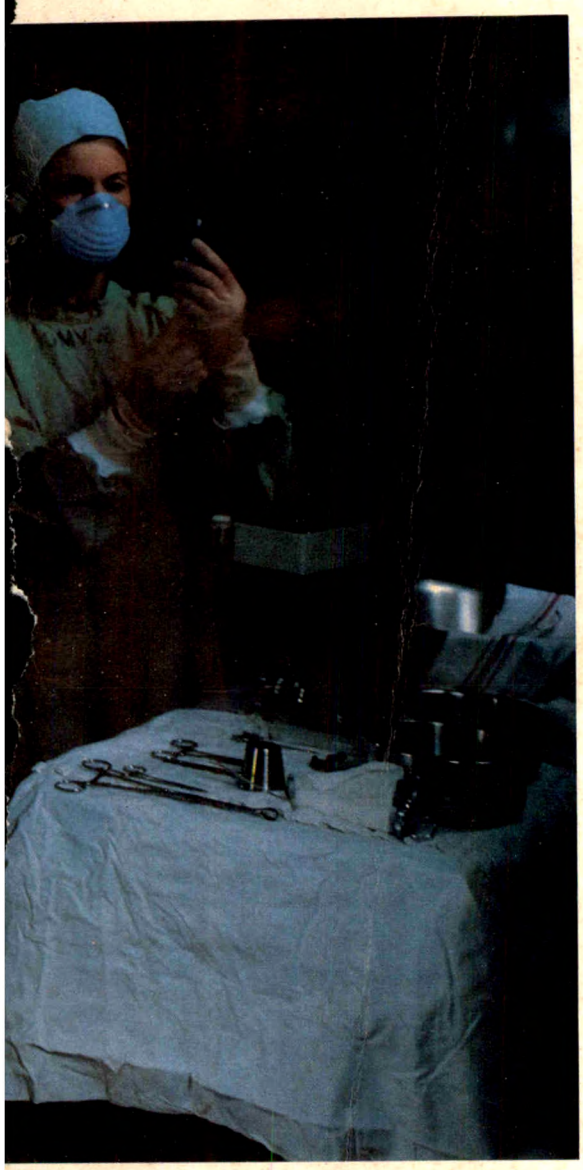
TOTALLY DIGITAL CORONARY

Superior images with high frame



IT'S WHERE IMAGING IS GOING...

ARTERY IMAGING...AngioVue.™
...ate processing and image enhancement.



Coronary artery imaging with a totally digital system.

Diasonics' new AngioVue Digital Angiography System produces digital images clinically equivalent to cine film through digital image manipulation and image enhancement algorithms. The AngioVue allows clear visualization of coronary arteries with fine detail. It's all possible through Diasonics' unique pulsed mode digital acquisition gated at 8/fps with 512x512 resolution—and totally digital storage.

Faster, more accurate, quantitative ventriculography.

By combining superior digital images acquired at 30 fps and powerful computer analysis, faster, more accurate ventriculography is performed.

Through standard area length techniques and densitometry, AngioVue provides easy calculation of ejection fraction, C.O. and C.I. Diasonics' advanced software allows segmental wall motion and functional image analyses. And, with its 256x256 matrix, ventriculography is performed with better resolution than nuclear cardiology.

Now, digital angiography for all cath lab imaging procedures.

With the Diasonics AngioVue, you can more effectively perform functional studies, PTCA, drug therapy and vascular imaging. You use less dye permitting more injections with less risk to the patient. And AngioVue interfaces directly with your existing equipment and can provide dual room and biplane capabilities.

Consult a Diasonics professional.

AngioVue brings to the cath lab the most advanced digital imaging technology available, with all the benefits of computerized analysis and the flexibility to meet your future needs. For a complete review of the AngioVue, consult the Diasonics professional in your area.
